

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

INDEX VOLUME VII.

	PAGE.		PAGE.		PAGE.
Apoplexy, penetrating wounds.....	593, 606	Association of American Physicians, 16, 25, 44, 110, 167		Bruen, diaphragmatic pleurisy.....	44
Abdominal section.....	624	Asthma, cause and treatment.....	495	Buboes, subcutaneous treatment of.....	214
Abortion, assaefetida in.....	573	Atheroma, recurrent, of uterus.....	690	Buck, operations on mastoid.....	103
ethics of.....	505, 599	Atkinson, rôtheln.....	299	ulceration of membrana tympani.....	162
viburnum in.....	352	Atropia, antagonism to morphia.....	658	Buckham, importance of prophylaxis.....	680
Abscess, hepatic.....	212	Aural, naso-, catarrh.....	496	Burnett, black cataract.....	584
mammary, abortive treatment of.....	178			inflammation of the attic tympani.....	164
of mastoid cells.....	164			Byford, pelvic hæmatocoeles.....	246, 333
ovarian, with pyo-salpinx.....	419			retroversion of uterus.....	147, 159
pelvic, laparotomy for.....	188			Byrne, galvanic-cautery in proclitidia.....	442
Abscesses, iodol in.....	610				
lumbar.....	449	BACILLI, tubercle, in Addison's disease.....	180		
Acne.....	365	Bacillus, of malaria.....	392	CABINET, pneumatic.....	211
treatment by sounds.....	304	typhoid.....	43, 50	Cæsarean operation.....	446
Acorn cocco, in diarrhoea.....	573	Bacterio-therapy.....	126, 460	Sänger's.....	135
Actinomycosis.....	384, 608	Badal's operation.....	235	Caffeine, as a diuretic.....	378
Adams County Medical Society.....	308	Baer, fibro-sarcoma of ovary.....	524	in heart disease.....	658
Addison's disease, tubercle bacilli in.....	180	monocyst of ovary.....	525	Calculi, large.....	108
Adenoma, of cervix.....	326	bursting cyst of ovary.....	525	urethral.....	702
Agaracine, uses.....	630	Baker, electrolysis.....	443	Caldwell, hernia of umbilical cord.....	104
Aged, pneumonia in.....	425	Bandl, Prof.....	392	Cambridge, bequest to.....	692
Air-passages, upper, catarrh of.....	495	Barker, maternal impressions.....	441	Campbell, Bartley.....	418
Albumin, bearing on life insurance.....	129	Barnett, salicylate of ammonium in fevers.....	654	Canabione, doses and use of.....	630
nitric acid test.....	322	Bartlett, dermoid cyst complicating labor.....	130	Cancer of kidneys.....	281
Albuminuria, experimental.....	154	modification of Porro operation.....	385	of lips.....	302
Alcohol, effects of.....	601	placenta prævia.....	130	of mamma.....	277
Alcoholism, strychnia in.....	59	Barton, tumor of stomach.....	76	of skin.....	302
Alimentation, artificial.....	165	vertical extension in fracture of femur.....	625	Carbolic acid, abuse of.....	53
Allen, Van, asthma.....	495	Batchelder, vaccination.....	513	injections in carbuncle.....	59
Aloin, uses.....	630	Baths, in cholera infantum.....	58	Carbuncle, carbolic injections in.....	59
Alopecia, prematura.....	527	Bauer, laparotomy.....	165	treatment of.....	366
Alt, trachoma.....	544	Beef, poisoned.....	613	Caries, excision of scapula for.....	574
Althaus, cerebral syphilis.....	472	Belfield, digital exploration of bladder.....	253	of parietal bone.....	385
Aluminium bronze.....	39	supra-pubic cystotomy.....	273	Carpenter, insanity.....	225
American Gynecological Society.....	413, 436	Bergh, on Pasteurization.....	82	Casseberry, galvanic-cautery in nasal and pharyngeal disease.....	412
officers.....	442	Bermann, nasal polypus.....	247, 277	Castration, in nervous and mental disease.....	547
Dermatological Association.....	298	Hert, Paul, death of.....	644	Cataract, after-treatment.....	636
Medical Association.....	409	Biliary obstruction, relation to glycosuria.....	208	black.....	584
officers.....	523	Billings, urine tests.....	527	extraction, cocaine in.....	203
plan of organization.....	706	Bishop, alopecia prematura.....	527	Catskills, excursion to.....	82
sections.....	381, 503	operations on drum for deafness.....	332	Cerumen, black.....	390
Otological Society.....	161	Rismarck, on State medicine.....	195	Cervix, adenoma of.....	326
Pharmaceutical Association.....	476	Bismuth, salicylate.....	630	division of, in antelexion.....	415
Public Health Association.....	325	therapy.....	123	in dysmenorrhœa.....	415
Rhinological Association.....	494	Pixby, Dr. S. N., obituary of.....	111	laceration, treatment.....	416
Ammonium, salicylate, in fevers.....	654	Blackburn, collapsed lung.....	666	splitting, fatal.....	50
Amputation, at hip-joint.....	206	enlarged spleen.....	666	Chadwick, blue color of vagina.....	445
re-injection of blood after.....	179	Bladder, digital exploration of.....	253	Charities, abuse of.....	605, 696
Anacharis alsinastrium.....	266	diseases, galvanic-cautery in.....	228	in New York.....	418

No. I.

ADDRESS IN DISEASES OF CHILDREN.

*Delivered at the Thirty-Seventh Annual Meeting of
the American Medical Association, in
St. Louis, May 7, 1886.*

BY W. D. HAGGARD, M.D.,
OF TENNESSEE.

CHAIRMAN OF THE SECTION OF DISEASES OF CHILDREN.

MR. PRESIDENT AND GENTLEMEN:—In obedience to a time-honored custom, and in accordance with a by-law of this Association, I appear before you as Chairman of the Section on Diseases of Children, to note the advances and discoveries of the past year, which, like those in all other branches of scientific investigation, move slowly but steadily forwards; each investigator adding his mite to what was known before. We are here to-day, in this growing and prosperous city, from the North, East, South and West, as guardians of the health and lives of the people. We are assembled together for the purpose of uniting in an honest, earnest endeavor to utilize the knowledge which the advances of the recent past have shed upon the problem of life. We live in an age of progress, characterized by the most effective effort that has ever been put forth to place a proper estimate upon the value of life, to increase its duration, and to elevate humanity to the highest standard of physical, mental and moral grandeur.

The Section on Diseases of Children embraces the largest and most important field connected with the workings of the Association, and should enlist the most earnest attention of every member of the profession. I trust, therefore, that it will not be in vain that I bespeak your indulgence while I enter a plea for the fuller recognition of this branch of our work, and beg your coöperation in the endeavor to secure a safer passage across the tempestuous sea from infancy to childhood, and from childhood to adolescence.

The last year has not been fruitful in advances sufficiently tangible to admit of specification, and yet, perhaps no single year from the foundation of medicine to the present has been so rich in fruitage; so far-reaching in its influence upon both the profession and the laity. No year's work has so indelibly impressed the mind of the profession on the importance of results accomplished—not in this nor that particular branch of medical science, but upon the better and more definite understanding of the great principles underlying the whole superstructure of scientific medicine.

I shall endeavor to bring prominently before the mind of the profession the vast importance of this department, not only to that portion of the human family to be directly benefited by future advances and discoveries, but likewise to point out and emphasize the fact that in the great mortality of children society, the State, the Nation; yea, the world, are all much more largely interested in lessening this fearful mortality, than those who perish in infancy, for they are perhaps the gainers. I need not stop to discuss the fact that the diseases of children have been most sadly, if, indeed, not most culpably neglected, from the earliest records of medicine to the present time, for this is patent to every open-eyed physician. There is not a single branch of medicine; nor, indeed, of any of the collateral sciences, which has not, from time to time, been made the subject of more special thought, scientific research, observation and experiment, than have the diseases of children.

It is true that every advance or discovery in scientific medicine has reflected progress on pediatrics, which has been indirectly benefited by the outcome of these improvements. The pages of history are full of instruction in the matter before us. Take, for example, the operation of ovariectomy, which has added in the aggregate so vastly to the span of human existence. Take the last twenty years of its history, so full of incident and interest, and link it with the lives of those most prominently identified with it, and it seems as if destiny herself, in her onward sweep has borne them through evolutions of thought, of science, of human effort and achievement, with a restless and unpausing zeal that has constantly led them forward, from one brilliant success to another, until the advance of abdominal surgery, like the sun at noonday, casts its effulgence from pole to pole and from centre to circumference. The outcome of this important operation has so captivated the minds of the more enterprising and ambitious aspirants for fame and fortune, that pediatrics has, for the time being, been thrown completely in the background.

Our profession, crowned with the marvelous achievements of the past, now looks, with a wistful eye, for investigators worthy of the past and prophetic of the future, as laborers in the field of pediatrics—men who possess the largest combination of successful elements, who are ordained by nature to lead into unexplored regions and dominate new fields of thought which will enable them to solve the problem now pressing for solution, viz.: to lessen this fearful mortality of infantile life. The cradle and the couch can

learn nothing of themselves; therefore we, who have copiously gathered from the experience of the past, must contribute to the advance of the future. When we consider that from one-fourth to one-third of the human family die under five years of age, the victims of disease, it seems truly that their lives are but as the sands upon the shore; their voices are but the evening zephyr, that dallies with the leaf for a moment, and passes away forever.

" 'Tis the wink of an eye, the draught of a breath,
From the blossom of health to the paleness of death."

It may be that it was the original purpose of the divine Creator to remove from earth to heaven this large proportion of the human family before they reach the age of responsibility. It may be there is a divine graciousness, an appropriateness, a grandeur, in the circumstance of the death of so many of our race during childhood. However this may be, we who have chosen for our lifework the amelioration of human suffering, cannot accept this dogma, for it neither satisfies the longings of nature nor the demands of the world. We must dive deeper into the mysteries of scientific medicine and prepare to grapple with that dread destroyer that claims so many of earth's little ones. Children typify the kingdom of heaven. They are the embodiment of all that is Godlike in man and beautiful in creation—the mystic link of holiness which unites man with the angels. What language can depict the anguish of a mother, as she lingers over the couch of a stricken child, and earnestly entreats the doctor to rescue her treasure from the ravages of death? Bright hopes and fond anticipations surround the cradle at early morn, the shadows of death gather over it at noon, and in the evening its occupant is a withered flower; the rosy cheek has changed to marble whiteness, "the silver cord is loosed, the golden bowl is broken, and the spirit returns to the God who gave it."

Every meeting of this Association brings us nearer the ark of safety found in preventive medicine, which is now extending its influence over every part of the civilized world, and is based upon the theory which was enunciated by Leeuwenhock in 1662. He discovered that the active principle in the process of fermentation depended upon a living organism; from which he concluded that the *contagium vivum* of all zymotic diseases must also reside in a vegetable parasite. Like discoveries in every other department of scientific investigation (notwithstanding every medical publicist since his time has had some opinion to express upon it), this theory was slow to secure that recognition to which its merits entitled it, being repeatedly forgotten and again revived until it was finally established that there are three distinct forms of parasitic life, viz.: vegetable, animal, and those that lie between the two. The vegetable form are of the nature of algæ or fungi, and are found in air, water, food and soil of all countries and climes. They are found on the highest mountains and in the lowest dells, riding upon the dust, the motes and the insects that float in the sunbeams.

From the day of Leeuwenhock to the present, the great effort of scientists has been to establish the causative relation of these organisms to the diseases

in which they are found. This achievement was reserved for the present generation. The labors of Pasteur, Koch, Klein and other famous scientists, by the revelations of the microscope, have established the causative relation of micro-organisms to the infectious diseases of insects, plants, and animals, man included. Pasteur, pushing his investigations still further, has established beyond dispute the fact that the microbes found in the various tissues of the body, in certain infectious diseases of animals, can be carried through a series of culture, until they are completely dissociated from the individual tissue in which they were originally found, and the primary disease be reproduced by inoculation. The microbes which have been produced by this system of cultivation have been proven, under the microscope, to be identical with those found in the tissues of the body both before and after culture; thus proving, beyond question, the causative relation of these organisms to the diseases in which they occur.

These experiments have been made over and over again, with uniform results, in chicken cholera, murrain, splenic fever, etc. The rapidly accumulating evidence in favor of the theory rests upon the experimental researches above referred to, and the great avidity with which the medical mind has seized upon these disclosures is, to me, one of the most hopeful signs of advancement. If the germ theory be correct, each of the specific diseases has for its origin a specific parasite, capable of producing the disease in individuals not already protected by a previous attack, vaccination, inoculation or idiosyncrasy. Whenever the conditions requisite to the development of the specific germ of any of the zymotic diseases are fulfilled, whether these conditions depend upon telluric, atmospheric, or some other influence, they must exist. Once in force, the action of the specific poison takes effect on those individuals whose resisting power, either from enfeebled development or disease, is least. In severe epidemics, these influences grow more powerful from day to day, until those whose resisting power is least succumb to the disease. The crowning glory of medicine in the nineteenth century is the effort to perfect the system of sanitary science and to improve the physical and intellectual powers of man. To this end the public health associations, the innumerable county, city and State Boards of Health, as well as the best scientific ability both in and out of the profession, in all parts of the world, are lending their most earnest and zealous efforts.

As a result of these efforts, we find the annual report recently issued by Dr. William Ogle, of the Statistical Department of England, shows a decided diminution, in the last ten years, in the mortality due to the various zymotic diseases. The report shows conclusively that the decline is due to the diminished mortality among children of tender age. It appears from the following extracts that the annual deaths from scarlet fever have fallen from 972 to 716 per million; those from diphtheria from 185 to 121; those from bowel affections from 1,076 to 935. This is really a very satisfactory showing, when we consider how slow the vast majority of mankind (professional and unprofessional) are to accept any new dogma.

The report contains much valuable information, but as our paper is only to show that the diseases of children which are attended with the greatest fatality are being brought under such sanitary conditions as tend to lessen the mortality, we will follow it no further.

If we accept the estimate of statisticians of the actual cash value of each male and female who live to attain adolescence at one thousand dollars, then add to this financial value the intellectual worth of hundreds of thousands of children who perish annually from infectious diseases—that are in the main preventable—we have but a faint conception of the vast loss the world sustains by this fearful mortality.

In view of all this, humanity is ready to bow at the footstool of science, and beg that the ratio between those who live and those who die at the tender age be diminished, and that they have thrown around them the protecting care of hygienic medicine. The progress of science in none of its departments has ever reached the highest degree of perfection by steady, monotonous and gradual advancement. For long it has appeared to be so, until some fortunate individual, endowed with rare genius, utilizing the knowledge gained from all sources, has evolved from the womb of time some hidden truth which in a brief period has effected more than years of patient toil, and marked his epoch as an era, sending his name across the empyrean of thought like a meteor flashing across the heavens, winning for science incalculable benefits, and for himself glory and renown.

ORIGINAL ARTICLES.

ON THE TREATMENT OF DIPHTHERIA.¹

BY DELASKIE MILLER, M.D.,

OF CHICAGO.

PROFESSOR OF OBSTETRICS AND DISEASES OF CHILDREN IN THE RUSH MEDICAL COLLEGE.

This paper is on the treatment of diphtheria. It is brief, for in this presence it would be inopportune to specify in minute detail all that would be required for the tyro. Nor shall your time be taxed by the recital of cases.

A summary of the treatment of diphtheria would hardly be intelligible without first defining in some particulars the nature of the disease. This will involve the question: Is diphtheria a local disease? If this disease consist essentially in the redness, swelling and soreness of the mucous membrane of some part of the throat, followed by the exudation and formation of a pseudo-membrane upon that part, then topical applications will constitute the rational and efficient mode of treatment.

The fascinations of science are liable to bias the mind and lead the judgment astray; as, for instance, the mycologist finds certain organisms—the bacterium termo and bacilli—in the pseudo-membrane in the throat; he observes further that these microbes multiply with great rapidity, and with the exudate

constitute the pathognomonic membrane of diphtheria. Moreover, he may trace these micro-organisms, as they penetrate into the tissues, enter the blood-vessels and lymphatics, and through these channels, he assumes the general system and distant organs become affected. If this be true, and the only mode of attack, then the doctrine that the constitutional symptoms are secondary, and arise from the migration of germs from their nidus in some part of the faucial membrane, must be accepted. Again, because the local symptoms are sometimes severe while the general symptoms are mild, it is held that diphtheria is a local disease.

Diphtheria a general disease.

1. It is characterized by a period of incubation.
2. The general symptoms appear before the local.
3. The introduction of the germs by inoculation upon a distant part of the surface is followed by the appearance of the false membrane upon the faucial mucous membrane.
4. The membrane may form, under favorable conditions, upon various parts of the body.

These assumed facts would seem to be valid reasons for the belief that the throat affection is a local manifestation of a general disease.

Diphtheria is not croup.

1. Diphtheria is infectious. 1. Croup is not.
2. Diphtheria is a general disease. 2. Croup is local.
3. Diphtheria is an epidemic asthenic disease.
3. Croup is a sthenic local inflammation.
4. Diphtheria may be followed by paralysis. 4. Croup not.
5. Diphtheria may be complicated by albuminuria.
5. Croup not.
6. The diphtheritic membrane involves the subjacent tissues. 6. In croup the exudate becomes a solidifying membrane upon the mucous surface.

In the management of diphtheria it is of the first importance to recognize the infectious nature of the disease. For the protection, therefore, of the healthy, isolate the sick. The room assigned to the affected should contain only the simplest articles of furniture. Carpets, curtains and upholstered furniture should be removed. The atmosphere of the apartment should be kept at a uniform temperature of about 72°, and good ventilation should be secured without exposing the patient to draughts of air.

After the termination of the case, the thorough disinfection of the room, bedding and furniture should never be neglected, and the same may be affirmed of the clothing and persons of the attendants, and of the convalescing patient, as well.

The indications of treatment may be formulated as follows:

1. Destroy the septic germs in the blood.
2. Eliminate effete material from the system.
3. Prevent the formation of, or remove the pseudo-membrane.
4. Control pain and restlessness.
5. Sustain the strength of the patient.
6. Prevent the sequelæ.
7. Perform tracheotomy (?) or intubation.

The asthenic nature of the disease should be borne

¹ Read in the Section on Diseases of Children, at the Thirty-Seventh Annual Meeting of the American Medical Association.

in mind, even in the earliest stage, that the treatment may be preventive of the possible sudden prostration which precedes the dangerous complications. The alimentary canal should be freely evacuated. This may be accomplished by exhibiting some unirritating agent, as castor oil, rhubarb, or a suitable dose of the compound cathartic pill ($\frac{1}{2}$ grain or 1 grain).

Keeping in mind the indications which have been tabulated, some combination of remedies may be devised which will meet most of the requirements of the case. And it is fortunate that the remedies from which experience justifies an expectation of benefit are not incompatible, and may therefore be grouped. It is also worthy of consideration, that medicines intended for children especially should be rendered as palatable as possible. For this purpose the syrup of lemon may be substituted for the glycerine and water in the following prescription.

The following prescription is suggested as an example of such combination:

- | | | |
|----|----------------------------|---------|
| R. | Tr. ferri chloridi..... | 3j. |
| | Potas. chlorat..... | 3ij. |
| | Acid hydrochloric dil..... | m xx. |
| | Tr. capsici..... | 3j. |
| | Morph. muriat..... | gr. ss. |
| | Glycerine..... | 3ij. |
| | Aq. destil..... | 3ijss. |
- M. S. Give a teaspoonful every hour or two or three hours, according to the urgency of the symptoms.

Of course the proportions of the several ingredients will be varied in different cases to adjust the doses to the age and condition of the patient. The directions for taking the mixture given above, however, convey but an imperfect idea of the most efficient mode of using it. The patient should be required to take a drink of water, then immediately take the mixture undiluted. By this mode several indications are fulfilled at one and the same time. An efficient local application is made to the throat each time the mixture is administered, and the constitutional tonic, antiseptic and anodyne effects are also secured. The water which was taken before the medicine will be sufficient to properly dilute the remedies in the stomach, and thus prevent any irritation of that organ.

In mild cases this prescription will fill all indications, and a large proportion of cases in which this treatment was commenced early will progress and terminate as mild cases, which under some other course would prove severe and endanger the life. It will be unnecessary to annoy the patient by making other local applications. Moreover, there is good reason to assume that the paralysis which is sometimes a serious complication during the convalescence is due to impoverishment of the blood, the restoratives contained in this mixture should therefore prove a powerful preventive of this complication. Experience justifies this expectation, for paralysis will be encountered but seldom during the progress of the disease or in the convalescence.

The same may be affirmed of the effects of this mixture upon the local symptoms and upon the formation of the pseudo membrane. The local pain, the congestion and swelling are relieved, and it is not unusual to see the forming membrane disintegrate

and disappear within twenty-four hours after commencing the treatment. The earlier suitable topical applications are made to the exudate the more easily may it be removed. Unquestionably the case is sometimes made worse instead of better by the frequent resort to the probang, charged with escharotics or irritating agents. Besides, the excitement produced by this procedure must result in injury to the patient, especially when force is required to overcome the resistance offered by the child from fear and dread of the operation.

The importance of surrounding the patient with a warm atmosphere has been asserted. It is also important that the air be kept moist. The inhalation of simple warm aqueous vapor will produce benefit by its solvent effect upon the exudate, and also by allaying irritation and discomfort of the fauces. While this is being done additional benefit will be attained by charging the vapor with some agent or agents of recognized power in resolving the membrane, and also efficient as antiseptics, as aqua calcis, eucalyptus, oil of turpentine. Pepsin or trypsin may have a beneficial effect in dissolving the membrane, when the ordinary remedies fail.

The steam atomizer will be found efficient in utilizing the vapor. After a certain age, no difficulty will be experienced in directing the spray into the throat. And even in cases of very young children, the timidity may be readily overcome by placing the atomizer when in use (and it should be in use while the false membrane persists) at a distance from the face, and gradually approximating it till the vapor is inhaled freely. The same object may be attained by causing the vapor, charged with the solvent, to rise from an open vessel placed contiguous to the patient.

Of albuminuria it need only be said that it is present in a large proportion of cases, and that while the kidney is large and pale, it is not indicative of the serious renal complications, as in scarlatina, and it is exceptional when any serious effects from it become chronic. Iron and chlorate of potash would seem to be indicated for this phase of the case, and these are contained in an eligible form in the prescription already given.

Too much stress cannot be laid upon the importance of sustaining the strength by the liberal use of nourishment. Though the patient may feel no desire for food, he may be induced to take it, if it is offered in a concentrated fluid form, which should be repeated at short intervals.

In conditions of great depression stimulants are indicated. It is a fact of common observation that alcoholic stimulants are well borne in diphtheria, and that intoxication is not likely to follow even the free administration of whiskey. So beneficial are stimulants, that the free use of spiritus frumenti is considered by some as specific treatment (?) in diphtheria. Under the same condition it will be natural to cast about for other active tonics, and quinine will be among those selected. That quinine produces any specific action in diphtheria is problematical, and when administered, it should be for its tonic effect.

Strychnia is the remedy frequently prescribed for the removal of paralysis complicating diphtheria, as

if this drug had some specific influence in restoring muscular power. Query—Can strychnia be relied on for restoring innervation in this, as in some other forms of paralysis? Are not the indications here first, to establish assimilation, and second, to improve the quality of the blood?

Galvanism is an agent of undoubted value in the treatment of these paralyses, by stimulating nervous power, by exciting muscular contractions and by increasing the nutrition of all the structures involved in the paresis.

Should tracheotomy be performed, even in extreme condition of the patient in diphtheria? It is true this operation has been performed many times when the patient was in great peril; and sometimes recovery has followed. It would be just to say that the recovery in at least a minor proportion of cases has been due to the operation. This, however, has happened so seldom that the procedure has long been regarded by the laity with disfavor; and were the whole truth stated, undoubtedly the profession regard tracheotomy as the forlorn hope. And furthermore, there is reason to believe that in a proportion of cases, the fatal result might have been avoided, had the surgical interference not been interposed.

When we review the past we can see but little in the results of tracheotomy that is reassuring. Any procedure, therefore, which promises equal benefits, and is at the same time free from the objections indicated, will surely be hailed as an improvement. Intubation, it is now claimed, offers these advantages. Since the revival of this procedure by Dr. O'Dwyer a little more than a year ago, it has been tested in many cases, and the results as reported have been so satisfactory as to encourage the hope that it will soon supersede tracheotomy, at least in the majority of cases. It is certainly free from the objections which render cutting so unpopular. The consent of the parents is easily obtained. No solution of the continuity of tissues is produced, to add to the complications which already exist. It is therefore bloodless. It is not particularly difficult of performance. The relief is many times immediate.

INTESTINAL ANTISEPSIS.¹

BY D. N. KINSMAN, M.D.,

OF COLUMBUS, OHIO.

Cathartics have constituted no small part of the means employed in all ages in the treatment of disease. They have probably introduced the treatment of more cases of disease than any other class of remedies. Having been universally used they must have been found beneficial or they would have fallen into disuse. Their salutary influence has been explained by saying "they corrected the secretions," "opened up the portal circulation," cleansed the "*primæ viæ*," that they acted by depletion, and derivation; that they stimulated the liver to increased secretion of the bile, and thus wrought out their errand of mercy.

¹ Read before the Ohio State Medical Society.

All this has been very satisfactory in times agone; but it is no longer sufficient for the demands of an exacting, if not an exact, professional science. Among cathartics, mercury in some form has readily held the first place, because it was easily administered, prompt in action and more certainly followed by good results than any other agent of this class.

Now is there any scientific basis for this confidence in the value of cathartics, and especially in the value of mercurials, or is it simply "a rule of thumb"? Is all which can be said on this subject contained in the maxim "*Experientia docet*"? Certainly there must be some reason for the use of these remedies aside from those already given, and it will be the object of this paper to see if it can be found out, and stated in clear and definite terms.

In order to get at the bottom of this matter let us take an inventory of the stock we have on hand, bearing on this subject. When we have accomplished this we shall find, I think, we can explain the beneficent action of cathartics, on the theory of antiseptics in a satisfactory manner, and at the same time find a solution for certain morbid processes hitherto imperfectly understood. We cannot hope to elucidate everything that lies in this direction, but we can perhaps "blaze a way" along which some wiser one will build a royal road.

Digestion is partially, not wholly, accomplished by bringing the food into contact with the unorganized ferments. These are ptyaline, pepsine, pancreatine, etc. Ewald says that at its last reduction digestion is a process of hydration. By the action of the saliva and the pancreatic juice, starch $C_6H_{10}O_5$ becomes $C_6H_{12}O_6$ or $C_{12}H_{22}O_{11}$, as the change results in glucose or maltose. By the action of the gastric juice albuminoids are changed into albuminose, or peptones. They are readily soluble in water, immediately absorbed, and cannot be recognized in the blood; being, as it is believed, reconverted into albumen. On the pancreatic juice we depend for still further action upon starches, the proteids, and fats. A peptone is produced in an alkaline fluid which differs but little from that produced in the stomach in an acid medium (Foster). Leucin and tyrosin are also produced from the proteids. The fats are split up into glycerine and acids, as well as emulsified by the action of the pancreatic secretion.

So much is accomplished in the process of digestion by means of the unorganized ferments. These are chemical agents, and as such can have but a single course of action, other things being equal. The organized ferments, of which we shall speak hereafter, may be modified in their action apparently in a variety of ways—either by the liquids in which they grow, the presence or absence of air, etc. The action of organized ferments results in putrefaction; while the statement is made on authority that the gastric juice *arrests* putrefaction. Whether this be so or not is not deemed important in this discussion.

Putrefaction, then, is the result of bacterial action. A great number of bacteria enter into this process. By their action starch is changed into sugar, and sugar is changed into lactic acid, butyric acid, and mucilage, alcohol into acetic acid, urea into carbon-

ate of ammonia, albumen into peptones and other similar products, and in the midst of this process other bodies are produced. These bodies are quaternary alkaloids of various chemical reactions; some are poisonous and some are not. They are now known as ptomaines. Besides these, indol, phenol, skatol, sulphuretted hydrogen, ammonia, carbonic acid, and water, are produced. This is sufficient to show that to some extent the process of digestion is similar to that of putrefaction. But putrefaction is due to bacterial action, and when we learn that indol, phenol, and skatol are produced in the process of digestion, as we call the reduction of the food in the stomach and the intestines, we are led to inquire if the digestion of the food is not supplemented by bacterial action in the intestines. Putrefaction cannot take place when bacteria are excluded. This is placed beyond dispute by the experiments of Koch, Pasteur, and others, and the whole doctrine of antiseptic surgery rests on this affirmation.

I think I shall be able to show that when digestion is not normally performed, it is fair to infer the anomaly does not depend upon variation in the quantity or quality of the gastric or other digestive fluids, but upon the subversion of the power of the normal fluids by intense bacterial action. In other words, the process is no longer one of digestion, but of putrefaction.

The specific action of a few bacteria is known. The bacillus amylo-bacter is everywhere the cause of butyric fermentation. It changes, starch, sugar and lactic acid into butyric acid. The lactic acid ferment, which is a bacillus, changes milk sugar into lactic acid. *Mycoderma aceti* changes alcohol into vinegar. These are but a few of the immense number of the bacteria in the stomach and intestines. The quantity of hydrochloric acid in the normal gastric juice is but .2 per cent.; when the proportion is increased to .6 per cent. digestion is arrested. When the fluids of the stomach become intensely acid, rise in the throat and set the teeth on edge, this acidity is due to bacterial action, or putrefaction of the food materials in the stomach. It is an evidence that putrefaction in the stomach and intestines is no longer supplementing the action of the unorganized ferments, but has taken its place. This bacterial action upon the food in the bowels is evidently much more important than has been usually supposed.

Duclaux says that the action of bacteria is as important as that of the normal intestinal liquids in the process of digestion in adults. There is reason to believe that all experiments which have been hitherto performed to ascertain definitely the action of the unorganized ferments will have to be considered anew, for it is now evident most, if not all, are vitiated by a failure to take account of bacterial action. It seems probable that most of the changes which occur in the intestines which have been attributed to the *succus entericus*, are due to bacterial action.

"The meconium contains no bacteria. Bienstock has isolated five different bacteria in the stools. Bacteria which are so numerous in the mouth do not pass into the intestines but are slain in the stomach by the gastric juice. There are five kinds of bacilli in

the stools. The first two determine no disease in mice; the third is pathogenic; its culture determines oedema and death in mice in twenty-four hours. The fourth and fifth are very important in the phenomena of digestion. They are not found in the stools of infants until after weaning." This, coupled with the statement of Senator that there is no indol or phenol in the intestines of the nursing infant, is important. "One of these bacilli decomposes albumen, the other hydro-carbons. *The first is not found in the stools of infants fed solely on milk.*" Hence there is neither indol or phenol in these stools, these products being the index of bacillar action or putrefactive changes.

Bienstock proposed the following questions: "Will the last two bacilli decompose sterilized albumen while the first three will not? Are products (indol, phenol, etc.) formed during the life of these bacilli by the decomposition of albumenoids and carbohydrates? Finally, whether it was possible to cultivate these bacteria to a state of purity, both before and after the decomposition of albumen? All of these questions were answered affirmatively. Bacillus number 4 always produced peptones from albumen and gelatine." I may remark here that the pancreatic fluid does not produce peptones from gelatine (Foster), and the products described by Nencki, Bauman, Salkowski, and others, (*i.e.*, indol, phenol, skatol). Bacillus number 5 by action on milk formed alcohol and lactic acid.

These bacilli decompose albumen and hydrocarbons in the intestines.¹ The *bacillus subtilis* produces peptones, as one of its functions in the process of putrefaction. In the germination of seeds we can study the action of bacteria upon starches, as we have studied their action in digestion. Germination is involved in putrefaction. "That which thou sowest is not quickened except it die." Bacteria, and not light, heat, and moisture, are the agents which inaugurate those changes in the seed which cause them to grow. They set in motion those forces which produce the blade, the ear, the full corn in the ear. Sterilized seeds were planted in sterilized soil, moistened by sterilized milk; all was enclosed in sterilized glass vessels, the openings to which were stopped with cotton. Air was thus allowed free access, but it was filtered from all bacteria. Under the most favorable conditions the process of germination was in abeyance for eighty-five days. The stopper of cotton was then removed, when at once germination begun.²

We have then found a solution for the production of diastase in the germination of seeds in the action of bacilli, a process hitherto most mysterious. Out of putrefaction life arises in the growth of the plant. So out of putrefaction—as well as digestion—arises the protoplasm which nourishes our bodies.

But digestion in the intestines not only produces that which, by absorption, builds our bodies; but in like manner poisons are produced which, in the mysterious economy of nutrition, are destroyed, when its processes are normal, or when they are disordered they accumulate and work mischief and death. In

¹ "Bacteria," Cornil & Babes, p. 124 et. seq.

² Progrès Médical, 1885.

the process of putrefaction poisons are elaborated which are deadly. Deaths from wounds infected with cadaveric poisons are sufficiently common to leave no doubt on this point. These are undoubtedly due to the bacteria. These alkaloids have been isolated from the putrefying flesh and injected into animals with fatal results. In like manner poisons have been extracted by dialysis from the contents of the intestines which have been injected into the bodies of animals with like fatal results.

Selmi and others assert that indol, skatol and phenol in the intestines are the indices of bacterial or putrefactive decompositions in the intestines. Of this there can be no doubt when we remember these substances are not present in the intestines of the young whose stools contain no bacilli.

If poisons capable of absorption are produced in the intestines, what becomes of them, and how is the system protected from injury? Schiff showed long ago that if the portal vein was ligated in an animal during the digestion of a meal, the blood in the right ventricle became intensely toxic, and this toxicity did not otherwise exist to so great an extent. He therefore concluded one function of the liver was the destruction of poisons which were introduced from the alimentary tract. Recently M. Rogers, studying the action of the liver on various poisons, has concluded, in accordance with the opinion of Schiff, that the liver arrests notable proportions of various alkaloids introduced into the organism, such as nicotine, strychnine, cicutine, veratrine, and caffeine. He has found the liver exercises a similar action upon alcoholic extracts of putrid substances, and intestinal contents. He has demonstrated that normally the portal vein contains toxic substances arising from intestinal fermentations.

In order to kill a rabbit weighing one kilogramme it was necessary to inject twenty-five cubic centimetres of dog's blood coming from the jugular or crural vein, eleven cubic centimetres from the portal vein, and twenty-two cubic centimetres from the hepatic vein. After intestinal antiseptics a dose of twenty-two centimetres was required of the blood of the portal vein. This author found that this function of the liver disappeared when it no longer contained glycogen.³

Indol, phenol and skatol are substances which enable us to recognize putrefaction, whether they are found inside or outside of the body. Indican in the urine is the index of the formation of indol in the intestines, and indol is due to bacterial activity. The urine of the newly born child contains no indican, and the meconium no bacteria and no indol. Hence it seems demonstrated that the urinary indican expresses the amount of indol absorbed. Indican is increased in the urine, in intestinal invagination and peritonitis, in typhoid fever, cholera morbus, cholera infantum, in the diarrhoea of consumptives, chronic gastritis, and cancer of the stomach and liver, as well as Asiatic cholera, dilatation of the stomach, and lenteric diarrhoeas.⁴

Indican is said to be increased in obstruction of the small intestines, and unaltered in that of the larger. Hence it becomes of value in the determination of the location of strictures of the bowel.

Bouchard has studied this subject clinically. He has found fresh faecal matters contain alkaloids in much greater quantity than the urine, and the richness of the intestinal matters in alkaloids is proportional to the intensity of the intestinal fermentations. In a case of putrid diarrhoea he estimated the proportion of bacilli at one-third of the mass, and the alkaloids at fifteen milligrammes per kilo, the urine contained forty or fifty times as many alkaloids as normally. Putrefaction in the intestines produces a large number of products, such as ammonia, marsh gas, sulph-hydric acid, butyric acid, lactic acid, and indol, phenol, excretive and quaternary alkaloids. Bouchard has introduced these matters into animals by the stomach, lungs, subcutaneously, or into the veins. Coma, convulsions and paralysis have succeeded large doses. In men headache, vertigo, ringing in the ears, deafness, fatigue, and depression of spirits succeed the administration of small doses. Intestinal occlusion and long retention of faecal matters increase the alkaloids in the urine, and are the symptoms of intoxication.⁵

Bouchard formulated three propositions:⁶

1. Alkaloids exist normally in the bodies of living individuals.
2. These alkaloids are found in the digestive tubes and are probably elaborated by the vegetable organisms which are the agents of intestinal putrefaction.
3. The alkaloids of the urine normally represent a part of the alkaloids of the intestines absorbed by the mucous membrane and removed by the kidneys.

On March 22, 1886, Bouchard continued a report of his investigations upon the poisons existing in the normal urine. He says the organism is fortified against self-poisoning:

1. By intra-organic oxidations.
2. By the liver, which arrests some and destroys others.
3. By the emunctories, which excrete them in great abundance.
4. The well-conditioned man produces in a mean of two days and four hours a mass of urinary poison sufficient to poison him.

The toxicity of normal urine has been demonstrated by intra-venous injection in rabbits, and it has been observed times without number in cases of urinary infiltration in the human being, who in the highest health has suffered from traumatism. "The symptoms following the injection of normal urine are contracted pupils, accelerated respirations, frequent urination, somnolence, diminished reflex action, and death without convulsions." This toxicity is increased by simple colds, any fever, or other indispositions. The toxic principle seems to reside in the coloring matter, for by passing the urine through animal charcoal its toxicity is diminished.⁷

The foregoing much too brief discussion I think

³ Progrès Médical, No. 8, 1886.

⁴ Arch. Gén. de Médecine, 1884.

⁵ Comby, Progrès Médical, May, 1884.

⁶ Progrès Médical, December, 1884.

⁷ Progrès Médical, loc. cit.

sufficiently establishes: that putrefaction plays no unimportant part in normal digestion; that this putrefactive process may exceed the bounds compatible with health, and even life; and that by a careful study of the urine we have the means in our hands which will enable us to recognize many hitherto unrecognized conditions as the result of auto-intoxication from products elaborated in intestinal putrefactions.

We shall now turn our attention to the investigation of certain diseases of the intestines, and see what can be learned of their special pathology. M. Damaschino reports observations made upon infants, in whom the matters passed are either green when they are voided or become so on exposure to the air. The latter form frequently runs into the former, and is not uncommonly the prelude of *cholera infantum*. When these green matters are spread upon a cover, stained with methyl violet, an immense number of bacilli are revealed, and their number augments as the affection becomes severe; as the disease declines the number decreases. These bacilli are never found in the cells or in the epithelial masses, but between them; they are sometimes united in an albuminous matter. The stools of patients with green diarrhoea have no resemblance to those of yellow diarrhoea in their bacillary contents.*

I may here remark that during the year 1885 I made many observations upon the stools of patients with diarrhoea, answering to the description given above, and can confirm its accuracy. I have further studied the stools of patients with *cholera infantum* and *cholera nostras*, and in both I was surprised to find the solid matter of the stools seemed to be composed almost entirely of bacilli instead of salt crystals, epithelial cells and intestinal mucus. In some of these cases I was able to detect a decided increase in the quantity of indican in the urine. This conclusion was confirmed by Dr. O'Brine, of the Ohio State University, who is an expert analytical chemist. In these cases, then, we have learned there are enormous numbers of bacilli in the intestinal discharges; we have also proven the presence of an increased amount of indican in the urine, two factors of great importance. From the statement of Damaschino, quoted above, we learn that in the green diarrhoea, which is frequently the prelude to *cholera infantum*, there is an immense number of bacilli; from other authorities we learn indican is increased in the urine in *cholera infantum*.

How are we to interpret the relation of *cholera infantum* and the bacilli? These are the agents of putrefactive changes in the food materials in the intestinal canal. In this putrefaction poisonous alkaloids are produced. These are absorbed and produce acute poisoning, as shown by diarrhoea, vomiting, and collapse. Should this seem a fanciful explanation of these conditions, when we have so often observed, either in our own practice, or read accounts of, cases of meat poisonings, which are due to flesh in the process of putrefaction, from which ptomaines have been extracted capable of producing similar symptoms? Heat cannot be ignored as a factor, but

it must rank as a predisposing cause. If anything more, why do not cases of *cholera infantum* occur just as frequently among children who are nursed at their mother's breast? The answer is this, as already quoted from the investigations of Bienstock: There are no bacilli in the intestines of children fed on *pure milk diet*; i.e., at the mother's breast; hence no chance for fermentation, and consequent poisoning from the products of fermentation.

When mixed food is used the possibility for pure feeding is gone. How often an outbreak of *cholera infantum* has followed the eating of a bad conditioned banana or apple. As we know that the agents which produce putrefaction are the same both inside and outside the body, we can understand why the introduction of swarms of bacilli into the intestinal canal by means of decaying fruits, would be fraught with greater dangers far to the child than its exposure to heat. Hence we conclude heat acts in producing *cholera infantum* by rendering bacillar infection of the intestine easier, rather than by overcoming the vaso-motor system.

In like manner we would explain the causation of attacks of *cholera morbus* and simple *cholera*. A ptomaine extracted from pure cultures of the *cholera bacillus* will produce all the phenomena of *cholera*, equally as well as the injection of the fluid from the intestines of the victims of the disease. Nor are the alkaloids produced in the intestines of the same kind always; as the bacilli may vary, so too may their products, and their effects upon the organization. Instead of vomiting, diarrhoea, and collapse, we may have headache, fainting, lethargy, palpitation of the heart, eructations, mental depression, distension of stomach and bowels, aching in limbs, and indisposition, as well as incapacity for muscular exertion, somnolence, etc.

But in all cases in which an examination of the urine reveals an increase of indican, we may with confidence attribute the symptoms to auto-intoxication from products of intestinal fermentations. While laying so much stress upon the action of the intestinal ptomaines, I ought perhaps to mention Gautier's new observations on the leucomaines—alkaloids which are produced in the normal disintegration of the body, which have been eagerly seized upon by the opponents of bacterial pathology to explain all forms of auto-intoxication. Manifestly they do not act as poisons unless they accumulate; when they accumulate they do not act as promptly or as energetically as the ptomaines, and at present the quantity of leucomaines known to exist at any time in the body has an almost insignificant relation to that of the ptomaines which may be extracted. After this the ptomaines and the leucomaines must be considered when the subject of uræmic intoxication comes up for discussion, and it seems to my mind very probable that the doctrine of the production of ptomaines by intestinal putrefaction is going to help us explain some of the phenomena which, under our present theories, are totally inexplicable.

How, for instance, can we explain the occurrence of convulsions in one case of uræmia, and their absence and a condition of coma in another case, if the

* Progrès Médical, December, 1884.

cause be the same in both cases? We know there are many varieties of bacilli in the intestines, and they produce many alkaloids. Some are harmless, others are convulsant, like strychnine, and others still, act like atropine. On the assumption of the formation of different alkaloids we can account for the various manifestations of intoxication when they are absorbed. Between the formation of toxic alkaloids and their fatal manifestation after absorption into the system, stands first the liver, which destroys notable proportions, as shown by Roger; then another portion eliminated from the blood by the action of the healthy epithelium of the renal tubules; and if in any case either of these guardians of the portal of life fails, the result is inevitable—death comes by convulsions or by coma.

Since writing the above Bouchard's conclusions from the study of the urine in the production of uræmia have come into my hands. They have not yet been published by him, and I have to take them second hand. I make the following condensation of his views, from a "critical review" of the subject.* Seven substances enter into the production of the phenomena of uræmia:

1. The diuretic, which is urea.
2. The narcotic, whose nature is yet unknown; all that can be said is that it is organic, not fixed by charcoal, soluble in alcohol.
3. A sialogue, organic; like the former, of unknown nature.
4. There are two *convulsants*. These do not manifest their action when the urine is injected, for the narcotic kills before they can act.
5. A substance which contracts the pupil.
6. Finally, there is a substance which depresses the temperature. After the injection of urine the animal cools.

Here is a scheme which includes all the factors which are necessary to explain a uræmic attack. The organic compounds creatine, creatinine, leucine, tyrosine, etc., have no effect. The potassic salts in excess have a poisonous influence. The scheme which he proposes for *pathogenic treatment* is: Hinder tissue metamorphosis, diminish the action of the liver, administer an aliment containing few minerals, oppose *intestinal* putrefactions.

I will cite some cases illustrating forms of intoxication from putrefactions in the intestines.

"A professor, æt. 38, robust, was taken during the night of the 4th or 5th of January with violent colics after having eaten and drunken copiously. He performed his duties the next day in school. The colic continued and became more violent; he went to bed in the evening, and when I saw him he complained of nothing but abdominal pains and diarrhoea. Pulse 76; skin moist; tongue coated; no appetite. No bad odor of breath; discharges odorless; belly not swollen, but resistant. Pressure is painful in the ileo-cæcal region, over a space the size of palm of hand. Low-pitched tympanitic sound here. Night disturbed by vomiting. In the morning patient had discharges with the odor of rotten eggs. I am able to confirm this assertion of the patient. While I

was examining him he tried to rise and fainted; his lips became pale, pulse frequent and feeble, sometimes not perceptible; pupils normal, reacting to light. This lasted a minute and one-half or two minutes. The patient recovering from this, complained of præcordial distress and clouds before the eyes. After this attack he had a discharge of urine with the odor of sulphuretted hydrogen, and it blackened acetate of lead. The weight and anxiety persisted. He had a similar attack in the afternoon. The urine no longer contained sulphuretted hydrogen. In the evening there was little fever; at midnight copious stool. Patient was well next day. Senator was of the opinion the sulphuretted hydrogen was produced by intestinal putrefaction, which determined all the symptoms."¹⁰

The above case is a fair example of intense poisoning from bacterial or putrefactive processes in the intestines, and illustrates the statement of Bouchard: If the poison produced in a day was at once absorbed death would result instantly.

Mrs. A., aged 30, supposed to have had an abortion a week previously; no flowing for three days. Vomits now and has constantly for several days. Nourished by peptonized milk by rectum. Pulse 110, feeble; skin pallid and moist; temperature normal. Lethargic, speaks only on being addressed, somnolent. Abdomen distended, no painful spots; tongue dry and coated; pupils dilated. Having in view the possibility of poisoning from intestinal fermentations, stopped all rectal alimentation, and gave gr. $\frac{1}{4}$ doses of calomel rubbed up with milk and sugar every three hours. This was continued for two days, when, the bowels having been freely moved thereby—as well as rendered antiseptic—the patient was relieved of all bad symptoms, and from this time made an uninterrupted recovery. The urine was not examined in this case.

How often in the "second summer" we observe cases like the following: Child, 18 months, weaned in early summer, begins to emaciate, vomits occasionally milk in curds, has pasty, greenish, acid stools, or when he eats meats they escape in the same kind of masses, and with little or no change of character by the action of the digestive fluids. There are attacks of diarrhoea, and the stools are composed of mucus, with small quantities of what seems to be fecal matter. The skin is pallid or sallow, flaccid and non-elastic. The abdomen is distended, the sleep disturbed, and there is grinding of teeth. Sometimes convulsions, at other times depressions with sweats.

Again, in adults there are cases of watery diarrhoea which persist for weeks and months in spite of simple evacuants and astringents. The stools are largely composed of bacilli, and the urine loaded with indican. Here small doses of mercury work wonders.

There is no doubt but the bile has an office in the prevention of intestinal putrefactions. We are all quite familiar with cases in which the stools remain clayey, which are also intolerably fetid. By common consent this condition has been attributed to the want of bile in the intestines, by failure of secretion or from

* Uræmia by Giraudeau. Arch. Gén. de Méd., 1866, p. 212, et seq.

¹⁰ Arch. Gén. de Méd., 1884, p. 484.

obstruction. Calomel or blue pill has been administered for time out of mind for this condition with favorable results. The benefits derived were supposed to be due to the action of calomel in increasing the flow of bile. Years ago the British Commission appointed to investigate the alleged cholagogue action of mercury reported that it had no such action; and yet the fact remains, established by the experience of hundreds of careful observers, that mercurials produce good results in such cases. Other theories rose to explain this benignant action of mercury. Bacteriological studies have led us to the conclusion that mercury, instead of increasing the natural antiseptic of the intestines, either directly or indirectly, destroys the bacteria, and thus performs for the system a duty which it can no longer discharge.

It has been long known that mercurials have a special action upon the small intestines. It is said they remove the excess of peptones, and thus relieve the headache, bad taste, aching in the muscles, foul eructations, abdominal distension and feeling of general malaise which so often follow the indulgence in a full banquet, washed down with "copious draughts of generous wine." This is due to the antiseptic action of the drug, for I have seen it produce the same result in doses much too small to produce catharsis. Other drugs fail to do this even when the catharsis has been prompt and voluminous. I know of no means so potent for arresting the fermentations which hold high carnival in the stomach and bowels of the patient who has been on a prolonged drunken spree as a mercurial. That bacterial action is raging, and is a cause of many, if not most of the nervous phenomena, any one who examines the ejecta from the stomach and bowels of such patients may easily learn. The bad odor of such patients is not due entirely to alcohol. In dilatation of the stomach and other affections we can use mercurials to advantage for their antiseptic action.

Liebermeister says, after having used calomel in about 800 cases of typhoid fever: "I have every reason to continue it and recommend it to others."¹¹ Whether calomel acts by elimination of the poison by its cathartic action or not Liebermeister does not say. But it does lower temperature, and reduces mortality. It has been used in doses of from gr. iv to xx. The examinations of bacteriologists and the general course of the fever lead us to believe that typhoid fever is of parasitic origin. Without pressing this statement, we all know that putrefactions are intense in the small intestines in this disease, and we can readily see that if mercurials are introduced into the intestines of patients they will act on the bacilli which are the cause of putrefaction, and thus remove one incident in the course of systematic poisoning which occurs in this disease. The testimony of Senator on the increase of indol in the stools and of indican in the urine, is conclusive, and enables us to thus explain the action of calomel in reducing the mortality of typhoid fever.

In the treatment of the early stages of cholera infantum mercurials have been used from the time they were introduced. Tho' some authorities write doubt-

fully of their value, there are but few who have not used them with advantage. Their value in this disease is to be attributed to their antiseptic or disinfectant properties, which thus prevent ptomaine poisoning. Other agents have been used in attempted antiseptic of the stomach and bowels. Mercury has been ever and is still the Samson of them all. Pumps and syphons drain, cathartics empty. Mercury kills the morbid agent on the spot, and destroys its producing power. Phenic acid, iodine, bromine, salicylic acid, thymol, and many other agents have been tried, but with no such results.

Bouchard has endeavored to draw therapeutic results from his researches. Since toxic matters are constantly pouring into the intestines he has endeavored to oppose their absorption by fixing these substances. In typhoid fever he has given charcoal in quantities of 100 grams daily, and has thus completely disinfected the typhoid stools; all the fetid substances which give odor to these stools are fixed by charcoal. Under this treatment the alkaloids in the stools and urine diminished. The power of charcoal for fixation will be comprehended when it is remembered that 100 grammes of this impalpable powder represents a surface of 60 square metres. Bouchard has also used iodoform in fine powder, so that a dose of 40 centigrams represents also a surface of about sixty square metres. We may by these means accomplish the antiseptic of the intestines.¹²

Of all disinfectants mercury in some form now holds the first place. Corrosive sublimate in a dose of 80 milligrams ($\frac{1}{8}$ grain) will sterilize a litre of meal juice which is swarming with bacteria. This is a large dose of corrosive sublimate by the stomach, but it has tremendous energy. It may, however, be given three times a day in this dose. Phenic acid to accomplish a similar work, must be given in a dose of 100 grains—clearly impracticable from its size if it was not at the same time poisonous. The same objections hold against all the other disinfectants.

I think we have arrived at bed-rock, and are now ready to formulate why mercury has been used and is likely to be used in all time, and also why it has done good and will continue to do good. I think that I may draw the following conclusions:

1. Digestion is due to unorganized and organized ferments, *i. e.*, bacteria.
2. Dyspeptic phenomena are probably due to bacterial action, *i. e.*, fermentations.
3. In these fermentations, ptomaines, indol, skatol, phenol, etc., are formed as in putrefactions.
4. The presence of indol, skatol and phenol is evidence of bacterial action, *a*, because in the meconium there are none of these products; *b*, they are absent in the stools of nursing children; *c*, in the urine of the newborn and the nursing child there is no indican; *d*, when these children begin mixed feeding bacilli appear, and with them indol in the stools, and indican in the urine.
5. These bacilli, while causing putrefactions, produce poisons, which are normally destroyed in the liver, or stored therein, or excreted by the kidneys and bowels.

¹¹ Zeimsen's Cyclopædia of Medicine. Vol. I, p. 201, et seq.

¹² Comby. Progrès Médical, May, 1884.

6. When the function of the liver is disturbed from any cause, so that the antiseptic action of bile is no longer exerted, the putrefaction and its products increase.

7. Mercurials, by arresting fermentations when in excess in the intestines, prevent the formation of ptomaines and autointoxication and supplement the action of the liver.

8. The beneficial action of mercury is due to its antiseptic properties.

9. Antiseptic medication is indicated in all cases when the indican is in excess in the urine.

MEDICAL PROGRESS.

DIAGNOSIS BETWEEN DISTENSION OF THE FALLOPIAN TUBES AND FIBROMYOMATA OF THE UTERUS.—

In a note on this subject Dr. P. HORROCKS says: The diagnosis of distension of the Fallopian tube, in the present state of our knowledge, is very difficult; indeed, those who have had the largest experience in operating for this disease, admit that they are never sure that the tube is diseased or distended until they have got it outside, through the abdominal wound. But this difficulty of diagnosis is due to the similarity between distension of the Fallopian tube and many other conditions, more especially pelvic cellulitis, pelvic peritonitis, and ovarian disease. It is, as a rule, not difficult to distinguish between fibromyoma of the uterus and distended Fallopian tube. The broad distinctions between these two conditions are as follows:

1. Fibromyomata, are usually accompanied by menorrhagia, and distensions of the tube are not.

2. Fibromyomata, especially when intermural, cause uterine enlargement; whilst, in distension of the Fallopian tube, the uterus is not enlarged, or only slightly, unless complicated by some other condition.

3. Fibromyomata are usually painless, except that there is often dysmenorrhœa (as in my case, published March 6), and, if large, a bearing-down pain, or sense of weight; whilst, in distension of the tube, the pain is constant throughout the intermenstrual period, aching in character, and aggravated by the menstrual period.

4. Nutrition is not much affected in fibromyomata, whilst it is in distension of the tube, especially when the distension is caused by pus; hence, wasting or loss of flesh is a valuable distinction.

5. The temperature is normal in fibromyomata, raised more or less according to nature and amount, in distensions of the tube.

6. Fibromyomata, when intermural, move much more rigidly with the uterus than distensions of the Fallopian tube.

7. Fibromyomata are much less painful, on pressure, than distensions of the tube.

8. Fibromyomata are usually much firmer in consistency than distensions of the tube.

9. Intermenstrual discharges, usually yellow, are

much commoner in distension of the Fallopian tube than in fibromyomata.

10. The position and direction of the uterine cavity is much more affected by fibromyomata than by distension of the tube.

11. Fibromyomata are usually more or less spherical, distensions of the Fallopian tube cylindrical.

12. Aspiration yields serum or pus in hydrosalpinx or pyosalpinx; and blood in fibromyomata and hæmosalpinx.

13. Distensions of the Fallopian tube are accompanied by pelvic inflammation much more frequently than fibromyomata.

These are, in my experience, the broad distinctions between these two diseases. Exceptional cases occur where the diagnosis is not so easy; but distension of the Fallopian tube is much more likely to be mistaken for some disease of the ovary or broad ligament, rather than for fibromyoma of the uterus.—*British Medical Journal*, May 1, 1886.

SUCCESSFUL EXTIRPATION OF THE SPLEEN.—*La Gazzetta degli Ospitali* (May 23) reports a case from the surgical clinique of the University of Genoa in which Professor A. Ceci removed a greatly enlarged spleen. The patient, an imperfectly developed and very thin girl, aged 17, weighing 40 kilogrammes, and 1.40 metre in height, with very small pulse, had had an abdominal tumor from birth. The transverse diameter of the tumor was 34 centim., the vertical 23 centim., and the circumference about 64 centim. The anterior surface was smooth and convex, the margins sharp and fissured. The posterior surface presented a large lobe on the left. The abdominal walls were very flaccid, so that the tumor could be completely rotated vertically and transversely, and also be pushed into the left hypochondrium, whence, however, the respiratory movements soon caused it to advance to the front of the abdomen. The liver was in normal position. The enormous size of the floating spleen interfered with the patient's movement and nutrition, and was an occasional source of severe attacks of pain, radiating from the left hypochondrium to the præcordial region and the left upper limb, and attended with violent dyspnœa and insensibility. Extirpation having been resolved upon, it was performed on March 20, with strict antiseptic precautions. The incision in the linea alba from above downwards through the umbilicus was 23 centim. (9½ in.) in length. On opening the abdomen, serious signs of suffocation compelled the suspension of the operation for nearly thirty minutes. Anæsthesia having been commenced with bichloride of methylene, chloroform was substituted for it. A triple catgut and carbolized silk ligature having been applied to the pedicle, it was dropped in. The peritoneum was sutured separately. The abdominal walls were brought together by three metallic points, after Billroth's method. The splenic artery was larger than the subclavian. The whole operation, including the whole interruption, lasted an hour and a quarter. Violent delirium and nervous phenomena simulating angina pectoris soon followed. For two days the pulse could not be counted, and the respiration varied from

70 to 80 per minute. The treatment was by oxygen and nutritive clysters. The wound was first dressed on the eighth day, and almost the whole of the wound-tract suppurred. In spite of strict antiseptic treatment erysipelas supervened, and yet the patient recovered. On April 22 (thirty-one days after the operation) her condition was reported as excellent, only a small superficial wound remaining. The extirpated spleen, with the contained blood, weighed 2400 grammes, equal to 37,036.8 grains, or 77.16 ounces. A courteous note just received from Professor Ceci states the patient is in good health; pulse 80; respiration 22; weight increasing rapidly; complexion florid.—*Lancet*, June 5, 1886.

PHOTOGRAPHING THE RETINA OF THE LIVING HUMAN EYE.—A paper with this heading appears in the *Photographic News* of May 7, by MR. W. T. JACKMAN, of Coggleshall, Essex, and MR. J. D. WEBSTER, and the authors of that paper have been kind enough to forward to us specimens of the photographs they have obtained. The difficulties of making a good photograph of the fundus are extreme, and we can only congratulate these gentlemen on the results of their labors, though it must be admitted that, as yet, it only appears to be possible to obtain a picture of the optic disc and of the retinal vessels as they cross the disc. The first experiments of Messrs. Jackman and Webster were made by placing a small camera fitted with a 2 in. lens in the place of the observer's eye behind an ordinary ophthalmoscopic mirror, but subsequently various modifications were introduced which are fully detailed in the paper referred to. The best light was found to be an alcoh-carbon gaslight, having a reflector behind it and a bull's eye lens in front. It was well borne by the eye. The reflection from the surface of the cornea was long found to be very embarrassing, but it was overcome with the exercise of a little ingenuity. In the photograph we have received, the physiological cup in the centre of the disc is very perceptible with the marginal portion of the disc, and the main blood-vessels and their primary divisions are distinctly marked. The result is sufficiently encouraging to lead us to recommend the authors of the paper to persevere in their efforts, and not to be discouraged by failure. Much greater difficulties than those which are here presented have been overcome by patience and the intelligent application of existing knowledge, and we expect soon to receive a still more satisfactory representation of the fundus of the eye.—*Lancet*, May 29, 1886.

OPERATION IN HYDATID DISEASE OF THE LIVER.—DR. SPISHARNY, of MOSCOW, describes, in the *Vratch*, three cases under the care of Professor Sklifasovsky. All recovered. In one case, a cyst had already burst into the pleural cavity. The Professor is strongly in favor of free incision, and sewing of the wall of the cyst to the edges of the abdominal wound. Statistics are in favor of this proceeding. Neisser has collected 300 cases of hydatid disease of the liver treated after different methods, with Listerian precautions. The results were mostly unsatisfactory.

The majority of this series were treated by puncture. Better results were claimed in 1885, by the Mecklenburg physicians and surgeons, in a series of 132 cases. In twenty-five cases, the cyst was allowed to burst spontaneously; 52 per cent. of these died. In seventeen, the cyst was punctured, with 58 per cent. mortality. In twenty-eight cases, incision and fixation of the cyst-wall was performed, with only 20 per cent. mortality. Korach has employed incision in eighteen cases; in six of these, the incision through integuments and cyst-wall was done in two stages. All of these latter recovered; one out of the remaining twelve died. Incision is becoming the most popular method amongst Russian surgeons, who have considerable opportunities of studying hydatid disease in their wards. There can be no doubt that aspiration is a dangerous proceeding. Incision is generally satisfactory, provided that there is no cyst behind that which is opened. If there be another, or several other cysts, the risk of fatal suppuration will be very great.—*British Medical Journal*, May 8, 1886.

ON STRYCHNINE IN DIPSOMANIA.—In the *Vratch*, No. 10, 1886, p. 177, DR. U. M. POPOFF, of St. Petersburg, states that, guided by the works of Magnus Huss, Luton, Dujardin-Beaumetz, and others, he employed nitrate of strychnine in two typical cases of dipsomania, and obtained strikingly successful therapeutic results. In one of the patients a (very gifted man of letters, aged 40), the alkaloid was administered under the skin, in the dose of $\frac{1}{10}$ of a grain at first (during a drinking bout) daily, then every other day, then twice a week, etc. The patient ceased to ask for drink after the second injection; within the next two days, various morbid phenomena (headache, weakness, discomfort, etc.) disappeared. On subsequent occasions, a few injections of $\frac{1}{10}$ or $\frac{1}{5}$ of a grain of strychnine rapidly removed craving, anxiety, irritability, agoraphobia, and other premonitory symptoms of a threatening dipsomaniac attack. The patient each time rapidly improved in all regards, and felt desire for work and society. In another patient, dipsomania disappeared under the internal administration of strychnine, the alkaloid being given for the first two weeks in doses of $\frac{1}{10}$ of a grain, and for another two weeks in that of $\frac{1}{5}$, twice a day, in pills.—*British Medical Journal*, May 1, 1886.

EFFECT OF MENTAL OVERWORK UPON THE TEETH.—Among the hard-worked pupils of the Paris public schools, the teeth become deteriorated in a few weeks after entry. The second dentition is often premature. These observations confirm the statements of Dr. J. L. Williams, who has given great attention to this subject. He has shown that any mental strain shows itself upon the teeth in a short time, both in increased decay, as well as in increased sensibility of the dentine. Dr. D. M. Parker has reported that these same changes are always apparent in men who are in training for athletic trials. As there is not the slightest doubt of the accuracy of these observations, they show that these are matters which demand serious consideration from educators.—*Boston Medical and Surgical Journal*, June 3, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, JULY 3, 1886.

COLD WATER ENEMATA IN CATARRHAL
JAUNDICE.

As the subject of the treatment of catarrhal jaundice by enemata of cold water has been under discussion during the past few weeks in some of our contemporaries, it seems proper to call attention to a paper on "Epidemic Jaundice among Children," read by DR. A. Y. P. GARNETT, of Washington, at the meeting of the American Medical Association in Cleveland, in 1883. This paper was based on a number of cases treated by Dr. Garnett during an epidemic of acute jaundice in Washington in the summer of 1881, the epidemic being almost exclusively confined to children under 6 years of age.

Epidemic jaundice among children is of very exceptional occurrence. Von Scheupel mentions, in his article in Ziemssen's Cyclopædia, only one such epidemic, which was reported by Rhea, and Legg mentions only two—one in Essen, in 1772, reported by Brüning, and one in 1870, at Hanau, reported by Rehm—while from 1742 to 1872 fifty-six epidemics are reported among adults. Sir Thomas Watson mentions an epidemic which only affected young girls, and different writers mentions epidemics which affected men only.

The use of cold water enemata in catarrhal jaundice was first proposed by Krull (in the *Berliner Klinische Wochenschrift*, 1877, p. 159). His method is to inject from two to four pints of water at 60° and this is retained in the rectum as long as possible; the enemata being repeated twice a day if necessary. Dr. Garnett's method of treating his cases differed materially both as to the quantity of water used and as to the frequency of repeating the injections. His

cases being children under 6 years of age, it was considered most prudent to use but four ounces of the water at a time, and repeat once every four hours during the day. Löwenthal used one or two quarts at each operation, and repeated but once in twenty-four hours. In Dr. Garnett's opinion the plan of injecting a small quantity of the cold water and repeating it every three or four hours would prove more satisfactory, even in adult cases, than the method pursued by Krull and Löwenthal.

It need scarcely be said, however, that this should not constitute the whole treatment of this affection. An exclusive diet of milk, with lime water, and whipped albumen of egg, and an easily digested meat juice on commencing recovery, is of prime importance. When the temperature is high and the skin dry, the patient should be placed in a bath at 80° or 85°, or may be sponged with water at this temperature. Calomel must be regarded as the most useful drug in the treatment of this affection, and it should be given in small doses. While many prefer to give it alone, rubbed up with white sugar, in doses of one grain every one or two hours, others prefer to administer it in combination with bicarbonate of soda, ipecac, and a very small quantity of powdered opium. For a child 5 years old the quantity of calomel should be about gr. 1-24 to 1-16, with 1-10 each of bicarbonate of soda, and ipecac, and not more than gr. 1-40 of powdered opium; though the soda and ipecac may be given in larger doses. This may be repeated every three or four hours, with the certainty that free evacuations will be obtained. For adults the compound jalap powder is often most useful in causing such a downward pressure as to force out a plug of mucus which is obstructing the duct; but for children this must be regarded as a rather harsh remedy. But for reducing mucous plugs phosphate of soda must be regarded as one of the most efficient of all remedies, and may be given with arsenate of soda. It should be borne in mind that calomel is especially efficient when there is much irritability of the gastro-intestinal mucous membrane, and when given alone or in the combination described above vomiting rarely occurs.

It is also to be borne in mind that as a rule a sick child is almost always thirsty, and that its thirst is not quenched by milk. Nurses, and very many physicians, are too ready to give a sick child milk when it should have water. In the treatment of very many diseases of children the use of alkaline, slightly laxative mineral waters is of great importance. American writers have fallen into the habit of prescribing Ems, Vichy, Carlsbad and other waters which can-

not be readily obtained. The Buffalo Lithia, No. 2, and Bethesda waters of this country may be regarded as much more desirable from any point of view, and for chronic cases, we may add, the Kentucky Blue Lick, which is a sulphurous water. Lemonade is an agreeable drink for adults, but it is undesirable for children, and should never be given to anyone when an alkaline water is being used. Aërated waters and effervescing drinks are not so grateful to children as to adults, at least to children under 5 or 6 years of age, and unless constant nausea demands them they cannot be regarded as having any advantage over plain waters for children of any age. It should be remembered that in very many cases of constant nausea and vomiting the source of trouble may be found in the fact that the stomach is empty or contains a small amount of mucus. This is easily removed by the administration of repeated draughts of warm water, until the stomach is thoroughly cleansed; after which hot water may be given. The Buffalo water, mentioned above, is an exceedingly light water, and is very useful in cases of nausea.

Nitric and nitro-muriatic (Mettauer's) acids are often of great value in the jaundice of adults, but they do not seem to be suited for those cases occurring in children. Finally, may be mentioned Gerhardt's proposition to faradize the gall-bladder, and empty it by compression with the fingers, forcing the bile into the intestines and thus clearing out the obstructions. While it seems to be a dangerous practice even in adults, the successes seem to justify it in those cases.

EXCLUSIVEISM AND SPECIALISM IN MEDICAL ORGANIZATIONS.

That principle or feeling which prompts one man or class of men to assume superiority in some direction over his fellows, and therefore to assert exclusiveness in association, rank or privilege, is probably as old as the human race. In matters of State or politics, it underlies all forms of aristocracy; it prompts the religionist to say to his neighbor "stand thou there, I am holier than thou;" and it does not fail in prompting even men of science to think they have attained an eminence that lifts them so far above all others cultivating the same fields of human knowledge, that they must needs have exclusive social organizations for themselves.

The strong influence of this psychological principle has been well illustrated in the progress of medical organizations in this country. Although every State Medical Society in this country has shown a remarkable disposition to give the fullest opportunity

to those cultivating special departments of medical science or practice to present reports or papers regarding their own special departments at any regular meeting; and although the American Medical Association, as fast as new specialties were developed, added new Sections for the accommodation of their votaries, the same spirit of exclusiveism soon prompted each to seek an organization for itself; not for the purpose, as might be supposed, of accommodating *all* practising a certain specialty with more time and freedom of discussion, but directly for the purpose of including in its membership only those who had already gained reputation, that they might on the one hand, avoid the necessity of entering into discussions on a level with the common doctor; and on the other, to more effectually bar the progress of each new competitor in the same field. Hence each new special organization is formed by a few of kindred spirit meeting and selecting those they desire for comrades, inviting them to a subsequent meeting, when a constitution and by-laws are adopted with such provisions that all subsequent additions must be made by the nomination and election of those already members, or even by a small council or committee of censors. Consequently these, so-called, American Ophthalmological, Otological, Gynecological Societies, etc., instead of being composed of all the American ophthalmologists, otologists, etc., who might choose to join them, or a ratio of delegates chosen to represent all, are close corporations to be increased or perpetuated only by the gracious favor of the individual corporators.

The whole process is admirably illustrated by the last so-called National organization just completed, and the proceedings of which we give in the present number of *THE JOURNAL* under the modest (?) name of "*The Association of American Physicians.*" A few months since a dozen or possibly twenty prominent physicians in Philadelphia and New York held a conference and decided to form what was to be called an Association of American Physicians and Pathologists, which it was supposed would complete the circle of special organizations known to the profession. They selected a sufficient number, chiefly from the cities of Philadelphia, New York and Boston, to make seventy-four in all, effected a temporary organization and agreed to hold their first regular meeting in Washington, D. C., June 17, 1886. That meeting was held with the results to be seen in the regular report of the proceedings in the present number of *THE JOURNAL*. Fifty-six of the seventy-four selected were in attendance. A constitution for permanent organization was adopted, limiting the

number of members of the Association to one hundred and the honorary members to twenty-five; making it necessary that proposed new members must be nominated by two regular members, referred to the Board of Censors and elected at a subsequent meeting, and as a part of the qualifications it is required that the proposed members must have accomplished some scientific or professional work of importance. Another provision fixes the permanent place of meeting in Washington, D. C., the time the month of June each year, and the name of the organization "The Association of American Physicians."

Here are nominally seventy-four, but actually fifty-six presumably eminent members of the profession, forty-two of whom are from the cities of Philadelphia, New York and Boston, forming an association avowedly of so high an order that of the 40,000 American physicians (not counting surgeons and other specialists) only 100 can expect to be members at one time, and carefully guarding the door of entrance for the future, and yet so modest, that they adopt a name directly calculated to create the impression everywhere that this new society is simply an Association of American Physicians and nothing more. Surely this is a serious mistake. There should be something in the name to indicate the distinctively eminent character of the membership. Perhaps the most appropriate title would be "The Association of *Eminent* American Physicians." But if the extraordinarily frequent use of the word "*eminent*" in two or three leading medical journals in New York and Philadelphia and their echoes in Canada and elsewhere, during the past year, has rendered that word too monotonous, then follow the *News* and call it "The Association of American Clinicians and Pathologists," or even "The Association of Medical Experts;" something, at least, that will surely prevent so distinguished a body from being confounded with the great body of American practitioners. We trust when the members come together again next June they will lay aside that modesty so natural to men of true science, and not only correct the present error, but if they meet there in the Capital of the Nation all the other specialist organizations to form a Confederated Congress, do not permit the repetition of a similar mistake by calling it "The Congress of American Physicians and Surgeons," as has been proposed, and which would suggest to all the outside world only a gathering of ordinary members of the profession, but insist boldly on its being called honestly and plainly "The Congress of American Specialists." For it would be a sad reflection if, after assembling annually on the banks of the Potomac

and enduring a June sweat for a decade, they found themselves wellnigh forgotten, and all for the want of a title sufficiently distinctive to secure the attention of the learned in all parts of the world. Let no one suppose that the foregoing comments are prompted by any feeling of opposition to the new Association. We are perfectly willing that both specialism and exclusivism shall have fair play and an open field, but it is no more than right to claim that every ship should sail under its own flag.

A NEW WORK ON RENAL DISEASES.

The want of a good American work on renal diseases has long been felt. The average American physician is not usually an enthusiast in matters of pathology unless there be with it a judicious combination of practical therapeutics. And it may be said that renal diseases are the *bêtes noires* of physicians. Reference to the existing works on the subject will show that the subject seems to be in a sad, if not positively unintelligible tangle; and readers have often turned from the subject in despair, wondering why authors cannot agree, at least in the matter of nomenclature. And this has not been the whole grievance of the reader. He has read pages of partly unintelligible pathology only to find a few lines of the most general treatment—or to find that the treatment advised was contradicted by the pathology just read. But since the appearance of Ralfe's excellent work on "Diseases of the Kidneys, and Urinary Derangements," of Tyson's second edition of his "Practical Examination of Urine," and, lastly, of the work which is named below the physician may, for all practical purposes, discard other works of this character.

"Bright's Disease and Allied Affections of the Kidneys," by DR. CHARLES W. PURDY, of Chicago, is the most recent contribution to the literature of renal diseases. Physicians and pathologists will congratulate themselves and the author that he has published a work in which the anatomical divisions of nephritis, so incorrect and misleading, have been discarded. To those who do not know the author of this work, it will be a sufficient introduction to say that much of his special pathological investigation for this work was done in the Pathological Laboratory of the University of Aberdeen, with the aid of Prof. D. J. Hamilton. With one exception all the illustrations, which are excellent in every respect, are original. If there be any chapters in the book which are more especially worthy of notice, they are the chapters on "Scarlatinal Nephritis," and "Puerperal Nephritis." Scarlatinal nephritis has received more obscure treatment, and less treatment, at the hands

of authors than any other affection dependent upon renal changes, and Dr. Purdy has greatly cleared up the subject. On laying aside the book the reader will only regret that its scope is not greater; but as it is, it may be considered the best work of its kind that has ever been brought out in America.

AMERICAN MEDICAL ASSOCIATION.—All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

SOCIETY PROCEEDINGS.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

First Meeting, held in the Army Medical Museum, Washington, June 17 and 18, 1886.

THURSDAY, JUNE 17.—FIRST DAY.

The meeting was called to order by the PRESIDENT, DR. FRANCIS DELAFIELD, of New York.

The original members of the Association number seventy-five, the majority of whom were present. Of the 75 members 16 are from Philadelphia,¹ 16 from New York, 11 from Boston, 3 from Montreal, 6 from Baltimore, 2 from Washington, 2 from Cincinnati, 2 from St. Louis, 1 from South Carolina, 2 from Chicago, 2 from Albany, N. Y., 2 from U. S. Army, 2 from New Orleans, 1 from Colorado, 1 from Connecticut, 1 from Maine, 1 from Pennsylvania, 1 from Massachusetts, and 2 from New York State.

DR. FRANCIS DELAFIELD then delivered the

PRESIDENT'S ADDRESS.

He said: At the inauguration of a new Medical Association, it would seem proper for the presiding officer to say some words concerning the objects of the Association and the best methods of carrying these objects into effect. It was my intention to do this, but when I considered the character and attainments of those whom I was about to address, such a plan seemed to me unnecessary and even impertinent. We all of us know why we are assembled here to-day. It is because we want an Association in which there will be no medical politics, and no medical ethics; an Association in which no one will care who are the officers and who are not; in which we shall not ask from what part of the country a man comes, but whether he has done good work and will do more; whether he has something to say worth hearing and can say it. We want an Association composed of members, each one of whom is able to contribute something real to the common stock of knowledge; and where he who reads such a contribution, feels sure of a discriminating audience.

We are all busy men, working men, ambitious men. We all like to give instruction and gain reputation, and both of these we can do in the societies already existing, but we also want a society in which we can

learn something. And this, I take it, is the real object of the enterprise which we inaugurate to-day to form an "Association of Physicians and Pathologists," to which we may come year after year with the well founded hope that at each meeting we shall find something to learn.

Without further preface I shall ask your attention to a subject of much practical importance:

CHRONIC CATARRHAL GASTRITIS.

The fact that the lining membrane of the stomach is both a mucous membrane and an organ of digestion does, in a measure, confuse our appreciation of the inflammation of this membrane. We are apt to notice especially the disturbances of digestion and to include all the cases in the general class of gastric dyspepsia. But the lining membrane of the stomach, is in part, a mucous membrane. It is frequently the seat of chronic catarrhal inflammation, and it then behaved as do the other mucous membranes under the same circumstances.

The Lesions.—Whether we consider the cases which are found at autopsy in the hospital dead-house, or the cases seen during life in private practice, it is evident that in the majority of persons, the inflammation goes no further than to affect the function of the mucous glands. They constantly produce a thick tenacious mucus which adheres in a thick layer to the surface of the mucous membrane. Less frequently the mucus is thin fluid and is vomited. With such a change in the mucous glands, the peptic glands may also give evidence of disordered function, but it is important to remember that unimpaired gastric digestion is perfectly compatible with chronic catarrhal gastritis. Anatomically, in such a gastritis, the only changes which we find are an increased quantity of mucus, sometimes congestion of the blood vessels, sometimes pigmentation, an enlargement of the mucous glands, some swelling of the stroma with a little infiltration of pus-cells.

Less frequently we find more advanced changes. The connective tissues between and beneath the mucous and peptic tubules is increased in quantity, and the tubules deformed and destroyed. The stomach may be contracted or dilated. Or without any increase of connective tissue, the walls of the stomach may be relaxed and its cavity dilated.

First among the symptoms, comes pain varying from a mere feeling of oppression or discomfort to the most severe and agonizing pain. Most common is the feeling of uneasiness or discomfort, either following the ingestion of food, or occurring when the stomach is empty. It is not always easy to distinguish this from pain belonging to the small intestine or to the colon. Much worse is the severe pain, due in some cases, to the presence of food in the stomach; a pain which is often followed by vomiting. At first, it only comes on when the stomach contains a considerable quantity of food, but later continuing even after repeated vomiting so long as the smallest fragment is left. A pain so severe, that the unfortunate sufferer has no rest by day or by night, deprives himself of almost all nourishment and finally falls a victim to the opium habit.

¹ One of these is in the U. S. Marine Hospital Service.

Nausea and vomiting are also regular symptoms. The nausea belongs to the early morning hours. The vomiting is most frequently a vomiting of food either in considerable quantities, or vomiting kept up so long as the smallest particle of food is left in the stomach. In other cases, large quantities of brownish fluid, mixed with mucus and food accumulate in the stomach and are vomited from time to time. This is especially the case, when the stomach is dilated. Vomiting of pure mucus is seen in a few cases. Vomiting of blood, usually not in large quantities may occur. Regurgitation of acid fluid in the morning especially belongs to alcoholic gastritis.

Retention and fermentation of the food in the stomach are most common with the dilated stomachs, but are by no means confined to them. They are found often enough in other cases of chronic gastritis. Constipation seems in some cases to depend directly upon the gastritis and will disappear as this improves without the use of any laxatives. In the same way, there are diarrhœas which can be cured by treatment directed to the stomach.

Headache is a symptom. It may follow a variety of types, but perhaps the most common is that which comes on at intervals.

A general loss of health, of which emaciation and loss of muscular strength are the most prominent features, is found with the worst cases of the disease. Inflammation of the tongue and a variety of abnormal sensations referred to the throat, mouth and tongue, belong to some of the cases.

The course of the disease is naturally prolonged over many years, and interrupted by periods of improvement. The symptoms come on in attacks, at first not severe, not of long duration, easily relieved in a variety of ways. As the disease continues, each succeeding year marks a greater severity and longer duration of the symptoms. In some of the patients, the disease never advances further than to make them uncomfortable during a part of each year. In others, the general health is disturbed, they are unable to work, and become miserable, chronic invalids. In others, the excessive pain drives them into the morphine habit. In a few cases, the gastritis causes death.

In attempting to establish a satisfactory treatment for chronic gastritis, it is important to state as clearly as possible the problem to be solved. First, we must remember that all patients who suffer from gastric symptoms, do not necessarily have chronic gastritis. Besides those who have functional disturbances of the stomach, or cancer or ulcer of the stomach, we find many others, in whom gastric symptoms are due to diseases or other parts of the body. Anæmia, uterine disease, the neurotic and hysterical condition and constipation often behave in this way. In old people the function of gastric digestion is often impaired simply as a result of old age. To each one of these conditions belongs its appropriate treatment, but it is not the treatment of chronic gastritis.

Still further, we must remember that in many cases of gastritis, palliation of the symptoms is all that we can hope for. This is true of the gastritis associated with heart disease, emphysema, phthisis, cirrhosis, Bright's disease, gout, rheumatism and alcoholism.

It is also true of the cases in which the inflammation has gone on to the destruction of the peptic and mucus glands. After excluding all of these there remains a large and important group of cases of chronic catarrhal gastritis, in which we may hope not only to alleviate the symptoms, but to cure the disease.

It is evident from the nature of the disease that any treatment intended not merely to palliate, but to cure must be of long duration, and that it must be repeated from time to time when the inevitable relapses occur. The different plans of treatment which may be adopted are: 1, the curative treatment of climate and mode of life; 2, the regulation of the diet; 3, the administration of drugs, and 4, the use of local applications directly to the inflamed membrane.

I believe climate and mode of life offer the most certain means of curing chronic gastritis. It is unnecessary to lay down rules as to the sort of climate. The two points of importance are, first, the locality selected must be one where the patient can live an out of door life, and second, the patient must live in this climate, either for several years or for a considerable part of each year. Excellent as this method of treatment is, it is evident that it can be carried out only by a limited number of persons. The regulation of the diet is a matter which demands consideration in every case of chronic gastritis. In trying to ascertain the best way of feeding these patients, I have found only one satisfactory method, and that is to feed them experimentally with different articles of food, and then after an interval of several hours, wash out the stomach and see how thoroughly these articles of food, have been digested and removed from the stomach. After pursuing this course for a number of years, I have arrived at the following conclusions:

It is necessary that the patients should be well fed, a starvation diet never answers.

The stomach does not require any rest from the performance of stomach digestion, on the contrary, it is all the better for being called upon to perform its natural function.

The patients' own ideas as to what agrees with them are usually erroneous. They are apt either to starve themselves or to select the least nutritious articles of food.

The use of artificially digested foods, or of substances such as pepsin to assist stomachic digestion, is unnecessary.

The starches, oatmeal, cornmeal, bread, the cereals, the health foods are as a rule, bad. Portions of them remain undigested in the stomach for many hours.

Milk in adults is an uncertain article. It answers very well for some persons, not at all for others.

Meat is usually readily and well digested, but there are occasional exceptions to this rule.

Vegetables and fruits can be eaten, but the varieties must be selected experimentally for each patient.

I do not believe that any case of chronic gastritis is to be cured by diet alone. Even the exclusive milk diet while it often relieves symptoms is, as a rule, only temporary in its effect, so that the patient simply loses a certain amount of time by employing this instead of more efficacious plans of treatment.

The advantageous use of drugs belongs to the earlier stages of chronic gastritis. At that time they often palliate symptoms, and sometimes even seem to cure the inflammation. In the later stages of the disease their use becomes more and more unavailing. Yet the reliable drugs for this purpose are not numerous: The preparations of soda, potash and bismuth, the mineral acids, glycerine, sometimes carbolic acid, sometimes iodoform, sometimes the bitter infusions. If none of these answer, it is hardly worth while to look any further. If we can combine, with the administration of drugs the regulation of the diet and of the mode of life of the patient, then of course, our chances of success are much greater.

The use of local applications made directly to the mucous membrane of the stomach. This I regard as the most efficacious plan of treatment for those patients who are not able to leave home and seek a proper climate, but ask to be relieved without interruption to their ordinary pursuits. The local applications are readily made by the introduction of a soft rubber tube through the oesophagus into the stomach. Liquid applications are the best. They should be made in such quantities as to come thoroughly into contact with the entire surface of the mucous membrane, although the pyloric end of the stomach is the region where the inflammations is principally situated. They should be made at a time long enough after eating for the stomach to be as nearly empty as possible. For many cases warm water alone in considerable quantities is the only local application needed. In some, however, there is an advantage in medicating the water and for this purpose I employ a variety of substances. The alkalies, the mineral acids, bismuth, carbolic acid, the salicylates, iodoform, belladonna, ipecac, gelsemium, may each one be employed according to the particular case.

For the first week it is often necessary to put the patient on a milk diet, and this can be done even with those patients who, under ordinary circumstances, cannot take milk at all. Then after a time, to the milk we add one solid meal composed of meat alone. Next this single meal is increased by the gradual addition of fruits, vegetables, and bread. Then comes the giving of two solid meals a day, instead of one; then three solid meals, and now we get rid of the milk, in part or altogether.

For the first week of this treatment it is wise not to expect any special improvement. Indeed, even a longer time than this may try the perseverance of the physician and the confidence of the patient. Sooner or later, however, the expected improvement begins; the nausea and vomiting cease, the constipation or diarrhoea is improved, the flatulence is no longer troublesome, the headache becomes less frequent, and of more real value than these, the improvement in the general condition of the patient becomes evident. The color, the weight, the appetite, the sleep, the spirits of the patient, all show a change for the better. Of all the symptoms, the pain is the one which is apt to persist the longest.

For two or three months the patient has to be kept under observation, and the applications to the stom-

ach made by the physician. After this the patient is dismissed, but continues the treatment himself, first every other day, then twice a week, then once a week for several months. The regular relapses of the disease are managed in the same way, but are much more quickly relieved.

I have tried thus succinctly to lay before you the characteristics of a common and important disease, and yet a disease which seems to me not to meet the recognition and attention which it demands. If I can secure for the patients who are made miserable by it a more careful and intelligent management than they are now apt to receive, the purpose of this paper will be answered.

The Committee on Permanent Organization reported a

CONSTITUTION AND BY-LAWS,

which after several amendments, were adopted. The main provisions of the constitution are:

That the Association has for its object the advancement of scientific and practical medicine. It shall be known as the "Association of American Physicians," and shall hold its annual meeting in the month of June in the city of Washington, D. C.

That the proceedings shall consist of discussions on subjects of general interest in the departments of medicine and pathology; of original communications and of demonstrations of gross and microscopic preparations, of apparatus, and of instruments.

That there shall be members and honorary members. The number of members shall be limited to one hundred. Physicians of sufficient eminence to merit the distinction may, to a number not exceeding twenty-five, be elected honorary members, and as such shall be entitled to attend all meetings and take part in the proceedings, but not to vote upon business questions.

That nominations for membership shall be signed by two members, be referred to the censors, and be acted upon at the succeeding meeting.

The following nominating committee was then appointed, to report on Friday morning: Drs. James Tyson, A. Brayton Ball, George B. Shattuck, Frank Donaldson, and Hosmer A. Johnson.

DRS. S. WEIR MITCHELL and MORRIS J. LEWIS, of Philadelphia, read a paper on

TENDON-JERK AND MUSCLE-JERK IN DISEASE, ESPECIALLY WITH REFERENCE TO POSTERIOR SCLEROSIS OF THE SPINAL COLUMN.

The investigators believed that by their work had increased the knowledge of the symptomatology of this affection. It was stated that while a muscle or a nerve may be excited by both electrical and mechanical irritation, the former is to be regarded as a ruder agent than mechanical stimulus. In some cases electricity is inapplicable beyond a certain extent. It was held that the knee phenomena were a direct muscular response and not due to reflex action. The most delicate test for determining the condition of the muscle is by striking the stretched tendon. This can be done in various situations, as at the knee, ankle, elbow, and jaw. Every distant muscular exertion, such as winking, if accurately

timed, exaggerates these phenomena. To demonstrate this, the patient should lie down with the knee slightly bent. At the time that the tendon is tapped, or just before, the patient is directed to wink, and it will be noticed that the jerk is much increased. This is more beautifully shown in the act of phonation, the patient being directed to count strongly, bringing the whole chest into play at the time the test is applied. A decided sensation, such as heat, cold, or an injury, will increase the responsive power of the muscle or tendon which has been struck. Both the tendon and the muscle jerk are reinforced by irritation of distant parts. This reinforcement disappears when the muscles are cut off from the spinal centres.

A blow on the muscle causes the muscle-jerk to extend up and down, but not transversely. In some cases of disease this jerk is irregular. In addition to this contraction, the muscles may form a little eminence or mound, which disappears slowly. Late in ataxia this is unusually well marked. It is also observable in some healthy muscles.

The phenomena of reinforcement was attributed to an increase of tone in the muscle as a result of the distant irritation.

A tabular statement was then presented giving the results of observation in twenty-three cases of locomotor ataxia. In this table the various symptoms and signs presented were represented by signs. In this way the history of each case could be seen at a glance.

In selecting a decisive symptom by which to arrange the cases into classes, station, or the ability to stand, was selected. This can be accurately estimated by having the wall back of the patient ruled in inches. The examiner takes his place in front of the patient and directs the patient to keep his eye on a particular spot above the head of the observer. It is then noted how much he varies laterally with his eyes open. He is then turned so that the anterior posterior sway may be noted. The examination is then made while the patient has his eyes closed. Numerous examinations made by Dr. Guy Hinsdale show that the normal man does not sway over one-half inch laterally, and not over three-fourths of an inch in the anterior posterior direction. The normal man sways forwards first, and first to the right. When the sway is more than three-fourths of an inch in the lateral direction, or more than one inch in the antero-posterior direction, the case should be looked upon with suspicion, as indicating that the general health is disturbed, or that there is some disease interfering with the maintenance of the equilibrium. The cases were divided into four classes. 1. Those in which station was normal. 2. Those in which it was slightly impaired. 3. Those in which it was greatly impaired, and 4. The paralytic cases. In the cases examined the knee and ankle jerks and their reinforcement were absent at the time when the cases came under observation. The changes in the arm jerk seem to advance in the same way as the leg jerks, although they come on later. In the paralytic stage the muscle jerk is increased, although the reinforcement is absent. In the first stage of locomotor ataxia the tendon jerk is diminished or absent, while the rein-

forcement is fair. In the subsequent stages both the tendon jerk and its reinforcement are absent. The muscle jerk and its reinforcement continue normal through the first two stages. In the third stage, while the muscle jerk is normal, the reinforcement is absent. In the fourth stage the muscle jerk is increased while the reinforcement is absent. In the fifth stage the muscle jerk is diminished and the reinforcement is absent. In the sixth stage both the muscular jerk and the reinforcement are absent. The increase of the muscle jerk late in the disease may be due to some irritative changes in the muscle, but this has not been positively determined.

In regard to associated movements, in a certain proportion of cases, if the patient is directed to shut his right hand, the left hand will also shut to a certain extent, and if the patient is sitting down, the leg may be drawn up. This condition may become more marked as the ataxic condition has increased. Another symptom referred to, and which was considered a new symptom, was prominence of the eyeballs. While the condition is not as marked as in exophthalmic goitre, it is sufficiently distinct to be apparent if attention has been called to the matter.

DR. E. C. SEGUIN, of New York, suggested another possible explanation for the phenomena of reinforcement: that when the patient performs some movement, or when his attention is attracted by excitation of a sensory nerve, the cerebral inhibitory influence over the spinal cord is momentarily reduced and the reflex powers are raised for the moment. The reinforcement seems to be rather a negative condition.

DR. JAMES J. PUTNAM, of Boston, agreed with Dr. Seguin as to the possible explanation of the phenomenon of reinforcement. It seemed to him a mere matter of words whether we consider this due to withdrawal of influence from above or to an increase in the tonus of the muscle.

DR. H. C. WOOD, of Philadelphia, thought that this was more than a matter of words. The explanation of the knee jerk is based on physiological ideas. There are three classes of movements: the voluntary, the reflex, and movements originating in the muscle or in the nerve-endings in the muscle. Until the fact that the time of the knee jerk is so different from the time of the other reflexes is explained, we must admit that we have these three classes of movements. While it is possible that the movements in the muscle are the result of inhibition, we have at present no proof that such is the case.

DR. F. PEYRE PORCHER, of Charleston, S. C., read a paper on

TYPHOID FEVER.

The author described a method of treatment which he considered very satisfactory. As in all cases of high temperature there is costiveness, the result of the arrest of the intestinal secretions, he recommended a mild laxative at the beginning of the treatment. Any laxative may be employed. The following combination is useful:

R.	Rhei pulv.....	gr. ii-iv.
	Magnesia.....	gr. x.
	Hydrarg. chloridi mite.....	gr. ss-ii.

Sodii carbonatis..... gr. iv.
 Pulv. ipecac..... gr. $\frac{1}{4}$.
 M. Et. ft. pulv. No. 1.
 Sig. One powder every four or five hours as required.

In the treatment of typhoid fever, three things are to be considered: the necessity for maintaining the strength of the patient, the support of the system by the use of stimulants, and the morbid effect of high temperature. Special attention was directed to the latter element of the treatment. In reducing the temperature, the speaker had resorted to the use of ice-cold water, which was applied to the head, hands and arms by the use of towels wrung out of the water and reapplied as frequently as necessary. The applications are continued for ten to fifteen minutes, until the heat of the skin is reduced. The use of baths was considered objectionable on account of the difficulty of their application, and on account of the prejudice against them. He prescribes for internal use a fever mixture prepared somewhat as follows:

R. Potassii acetatis 3i.
 Liquor amonii acetatis..... 3i.
 Spr. ætheris nitrosi..... 3ss.
 Tinct. aconiti..... 3ss.
 Aquæ ad..... 3iv.
 Sig. A dessertspoonful in a little water every two hours so long as the fever continues.

Morphia or the bromides may be added to the above preparation. It may also be employed in other fevers. Hot pediluvia may also be employed. In malarial cases, quinia and arsenic are employed. Later the mineral acids are added. With reference to the use of stimulants, these may be continued as long as the tongue is dry. Oil of turpentine is often called for on account of tympanitic distension of the abdomen. It is also of value as an astringent and as a general stimulant. The speaker had treated thirty cases in private practice in this manner. Three died. In these cases there were causes sufficient to explain the fatal termination.

DR. JAMES TYSON, of Philadelphia, described a case under his observation, in which, to reduce the temperature, he wrapped the patient in a sheet which was kept constantly wet with ice water. This was entirely successful. In this case both antipyrine and thallin were employed, but although they promptly reduced the temperature, it soon returned to its original position. When it is necessary to keep the temperature continuously reduced, he considered some modification of the cold pack is the best method.

DR. JAMES T. WHITTAKER, of Cincinnati, remarked that we should not lose sight of the possibility that the high temperature may be nature's way of getting rid of the poison. It has been found that the virulence of the typhoid fever bacillus can be reduced by heat. It is also possible that the changes formerly attributed to heat may be due to bacilli.

DR. E. DARWIN HUDSON, of New York, said that when he assumed his duties at the Bellevue Hospital, he found a simple and successful plan of treating typhoid fever in vogue. He was confident that under that treatment the successes among the poor pauper class of patients in that institution are greater than among the private practice of many physicians. The treatment is almost negative, consisting in sponging

the patient every two hours during the continuance of the temperature above 102.5°, and adherence to an absolute milk diet. The only other measures employed are those directed to the relief of special symptoms occurring in the course of the disease.

DR. SAMUEL C. CHEW, of Baltimore, had employed with success quinia by hypodermic injection in order to reduce the temperature. It seems to have almost a specific action when used in this way. He used a solution of the hydrobromate, in which 20 minims represented 4 grains of the drug.

DR. WILLIAM H. DRAPER, of New York, remarked that there is perhaps nothing more fallacious than statistics in typhoid fever. Cases of fever not truly typhoid are confounded with typhoid fever. All have seen cases in which there was a continued fever, but in which the temperature did not run the typical course. In such cases, we have no evidence that they are cases of typhoid fever. Experience shows that the value of antipyretic treatment in typhoid fever may be readily overestimated. In the majority of cases the value of antipyretics is not so much in reducing the mortality, as in affording comfort to the patient. That it does this, no one can doubt. The mortality of typhoid fever in the majority of cases depends upon conditions over which a reduction of the temperature would have no influence.

DR. WILLIAM PEPPER, of Philadelphia, said that we have statistics showing the normal course of typhoid fever, which would make us slow to accept a mortality of 15 or even 10 per cent. as evidence of much success. He thought it doubtful if the normal mortality would be over 15 per cent. under good nursing. Successes vary. He had treated a series of 104 cases without a single death, and again had treated twenty cases and lost five. It is evident that in typhoid fever we have different sorts of fevers, and a remedy applicable to one set of cases may not be to another. An excellent rate of mortality may be secured by absolute rest from the first moment of suspicion, and a rigid diet of milk or milk diluted. In addition he believed that the abstraction of heat is of great value. He thought that some remedy directed to the constant and important lesion of typhoid fever, aids in reducing the temperature. His own preference is for the salts of silver. If the case comes under observation early, is put at absolute rest, receives proper treatment, the mortality should not exceed 5 or 6 per cent. In private practice he believes that it can be kept down to this.

AFTERNOON SESSION.

The first business of the afternoon was the discussion of the question,

DOES THE PRESENT STATE OF KNOWLEDGE JUSTIFY A CLINICAL AND PATHOLOGICAL CORRELATION OF RHEUMATISM, GOUT, DIABETES AND CHRONIC BRIGHT'S DISEASE?

Referee, DR. JAMES TYSON, of Philadelphia.

Co-Referee, DR. WILLIAM H. DRAPER, of New York.

DR. TYSON, the *Referee*, began by defining the dis-

eases included in the subject. The usual definitions of rheumatism and gout as general diseases with local expressions were given. Diabetes was subdivided into two varieties—the milder and the more severe form. The former consists essentially in a defect in that particular metabolic office of the liver by which glucose is converted into glycogen. It is due to overstimulation of the liver cells by the excess of absorbed glucose arising from the habitual over-use of saccharine and starchy foods. The more severe form of diabetes may be termed neurogenous, and is caused by some direct or reflex influence on the vaso-motor centre, whence arises a hyperæmia and accelerated circulation through the liver, as the result of which the glucose absorbed during intestinal digestion is carried too rapidly through the liver to permit its conversion into glycogen. To this is added, in advanced stages, glycogen resulting from the splitting up of the products of digestion of nitrogenous foods.

Taking up the discussion, first as to rheumatism and gout, the referee called attention first to the difference in the morbid anatomy of the two diseases, in the absence of anything specific or peculiar in the changes in the joints in rheumatism, while in gout there is the peculiar deposit of sodium urate in the joints or their vicinity. The composition of the blood is definitely altered in gout by the almost constant presence of an excess of uric acid in combination with sodium, whereas no change of corresponding importance is found in the blood of rheumatism. Heredity plays a much more important rôle in gout than in rheumatism, reaching, in the former, according to various observers, 50 to 100 per cent., while in rheumatism the maximum claimed is 34 per cent. The early age at which rheumatism presents itself as compared with gout implies a difference in the etiology, as does also the absence of renal and the presence of cardiac complications. Alcoholic liquors and over-indulgence in food have no influence in the causation of articular rheumatism. In gout they are all-powerful.

The exciting cause of rheumatism is always cold, dampness, or both. The cause of the explosion or the acute attack of gout is the cause of the disease itself, and is due either to the over-accumulation of uric acid in the blood, whether as the result of increased formation or defective elimination, or to diminished power of resistance of the organism through some accidental cause, atmospheric or physical.

Moreover, except in the case of salicylic acid, which is admitted by all to be useful in both affections, Dr. Tyson thought that the treatment required by the two diseases was different. The treatment of gout is eliminative, that of rheumatism is restorative. It is true salicylic acid is efficient in both diseases, but this is not sufficient proof that they are the result of the same cause, so long as that cause is so easily demonstrated in one and not in the other. Nor is the case strengthened by the theoretical reasoning which so well explains the action of salicylic acid—that it prevents the formation of uric acid in the blood by seizing upon the glycocine out of which uric acid is formed.

The relation of gout to that form of chronic renal disease known as chronic interstitial nephritis is a true correlation, since there is every reason to believe that the cause of gout is one of the causes of this form of chronic renal disease, so common in gout, and the evidence of renal disease is often found long before the gout manifests itself.

To estimate the relation between gout and diabetes it is necessary to remember that there are the two forms referred to. With neither of them is there any pathological relation. Between gout and the first or mild form of diabetes there is a clinical correlation, although many of the facts on which it has been founded the referee believed to be erroneous. Thus, although uric acid sediments are quite common in diabetes, yet careful quantitative analysis shows no increase in the amount of uric acid excreted. The uric acid sediments must therefore be the result of the excessive acidity so characteristic of diabetic urines, due to the fermentative processes.

Again, it is said the lithæmic urines often contain sugar. This he was confident was much rarer than is commonly supposed, because of the fact that uric acid reduces the salts of copper, and this reaction is mistaken for that of sugar. He thought that the inability of gouty persons to digest saccharine and starchy elements of food should not be regarded as a proof of clinical correlation, because it simply indicates a feeble converting power of the intestinal digestive fluids over the carbohydrates. In diabetes there is no defect of this kind. The carbohydrates are converted into glucose with facility. The trouble is with the liver, which is not able to reconvert the glucose into glycogen.

Between gout and the more severe form of diabetes, which is the result of disease at a point distant from the liver, there is no correlation either clinical or pathological.

Between diabetes and Bright's disease there is a relation of this kind. The effect of the circulation through the kidneys, surcharged with sugar alone, or with sugar, acetone and diacetic acid, is to irritate the renal cells and produce a degree of chronic parenchymatous nephritis instead of the interstitial nephritis which is so closely correlated with gout. From recent observations there is reason to believe that these changes take place in the kidney earlier than used to be supposed, and that albuminuria appears correspondingly early, either coincidentally or in alternation with glycosuria. The difference between the relation of gout to Bright's disease and to the more severe or neurogenic diabetes, is that in the former that which causes the gout causes the Bright's disease, so that there is a true correlation; whereas in neurogenous diabetes, it is a result of the diabetes which causes the renal complication.

As to diabetes and rheumatism, the idea that these two diseases are closely correlated has apparently received substantial support from the results of treatment of the two diseases by salicylic acid. Occasional reports as to the efficiency of salicylic acid in diabetes have acquired additional impulse from views which have recently been promulgated by Latham, who concludes on clinical grounds that there are two

forms of diabetes, one due to neurotic disturbances of the function of the liver, and the other to neurotic disturbances of the functions of muscle. As the result of the latter, glucose is formed in the muscles and passes thence into the circulation. This latter is so closely related to rheumatism that one degree of oxidation develops the *materies morbi* of rheumatism, and another develops glucose. Having shown also by the same reasoning that the administration of salicylic acid arrests the formation of uric acid, lactic acid and glucose, he thus explains the usefulness of salicylic acid in some forms of diabetes, and says that in doses of from 10 to 20 grains three times a day, he has seen it produce marked improvement. More recently, Holden reports the successful treatment of six cases of diabetes with salicylic acid.

The referee, whose experience with salicylic acid in diabetes had not heretofore furnished satisfactory results, had not yet had the opportunity of applying this more recent principle, that it is in the cases with rheumatic pains that it is especially serviceable. He held that until more cases were collected in which this principle of treatment was applied, the question was not ripe for decision. In a single case which had come under his observation in which it was claimed that salicylic acid had been very useful, the sugar had been found increased rather than diminished.

DR. WM. H. DRAPER, the *Co-referee*, said: It is fair to presume that this question would not have been propounded if clinical experience did not suggest it. It certainly is not yet justified by the present state of knowledge in pathology. Although the question is premature from a physiological point of view, it can hardly be regarded as without interest and possibly importance from a clinical standpoint. It is from this latter aspect that my remarks shall be made.

By gout is meant, I take it for granted, not simply the arthritic malady, but a diathesis which manifests itself through more or less well-defined derangements of nutrition, which give rise to a variety of secondary cerebro-spinal irritations and provoke definite structural changes in the blood-vessels, in the connective tissue of the parenchymatous organs and in the nervous system.

By diabetes we are to understand, I suppose, the more common and lesser form of that disease. The term rheumatism is so vague in its ordinary application that it is not easy to exactly comprehend exactly what is meant in this question. It is presumed that it covers acute articular rheumatism and the subacute forms in which the differential diagnosis from subacute gout is so difficult.

The form of Bright's disease is probably the form of chronic diffuse nephritis which is characterized by extreme sclerotic changes in the connective tissues of the kidneys and in the arteries, and by cardiac hypertrophy.

I think that the experience of most clinical observers will justify the statement that gout, rheumatism, diabetes and chronic Bright's disease are frequently associated, sometimes in the same individual history; more frequently in the histories of families. The as-

sociation of gout and even chronic rheumatism with chronic Bright's disease is very common in the individual, while the association of gout with diabetes or of diabetes with granular kidney, is not common. Chronic rheumatism may exist without even being complicated with gout or diabetes or chronic nephritis, but in families where the association of morbid phenomena can be traced, I think that it will be acknowledged that these diseases are frequently found in more or less marked alliance.

Granting this association, are there any facts to show their correlation? Are they reciprocal, interchangeable affections, transmutations of the same morbid process, and therefore recognizing a common determining cause as yet unknown?

The *first* fact that suggests the idea that they are cognate forms is that of heredity. First as to gout and diabetes. Glycosuria often recognizes a gouty ancestry, the term glycosuria being used to express the lighter form of the disease. In many cases the grave form of diabetes is not traceable to a gouty origin. The speaker had seen many cases leading him to believe that, excluding the cases of diabetes of nervous origin, careful investigation of the family history would reveal the presence of gout in the majority of cases. *Second*, concerning gout and rheumatism the fact of heredity as establishing a connecting link is not so evident, but it has been pointed out that articular rheumatism frequently occurs in the children of gouty parents. The influence of heredity in determining the association of the subacute form of rheumatism and gout cannot be positively decided.

Third, as to the frequent manifestation of heredity in the history of gout and interstitial nephritis, I think that there can be no question. This form of Bright's disease not only occurs as a complication of inherited articular gout, but is often observed in the members of gouty families who have themselves never exhibited any articular lesions. This is especially seen in the female line.

I wish next to call attention to the Association with these diseases of certain common derangements of nutrition. While it cannot be claimed that organic chemistry has as yet done more than formulate the general principles that gout and diabetes are associated with the signs of incomplete metamorphosis of the food elements, it is daily making progress in solving the complex processes by which each atom of carbonaceous and nitrogenous food is finally resolved into carbonic acid and urea. In these two diseases there is a diminished capacity for converting the carbohydrates. The occurrence of sugar in the urine of gouty persons is not infrequent, and of lithic acid deposits in the urine of diabetics is not infrequent.

Gout, diabetes and rheumatism in their treatment by medicines exhibit reciprocal relations. In these various affections the alkaline treatment is used with benefit. It is admitted that the value of the alkaline treatment in acute rheumatism is not sufficiently well established to justify the proposition that the disease is on that ground a correlation of gout. The value of salicyl compounds in the treatment of gout, diabetes and rheumatism suggests the idea that these diseases have something in common, either causal

or concomitant, which the preparations of salicylin antagonize.

The clinical observations which support the idea of a correlation of gout, diabetes, rheumatism and certain definite structural changes in the kidneys and blood-vessels, namely, the frequency of hereditary transmission in the same family and their occasional coexistence in the same individual, the common idiosyncrasy of a diminished capacity for the complete conversion of the carbo-hydrates and finally the common reactions which they exhibit to the same remedies, are of course open to criticism, but they nevertheless excite a reasonable suspicion that these diseases have at least certain common features which in all probability proceed from similar derangements of physiological functions.

This much it seems to me may be acknowledged even in the absence of any pathological evidence that these diseases are attended with any common structural lesions or specific functional disturbances. There are many unsolved problems in the pathology of gout, diabetes, and rheumatism, and the working hypotheses of the clinical observers in this field are being constantly unsettled by the revelation of the physiological laboratory. It would seem, therefore, that the only conclusion we are at present justified in making as to the correlation of the diseases in question is this: clinically, they are often associated by hereditary transmission, by coexistence and alteration in the same individual, by presenting similar idiosyncrasies in regard to the power of converting the carbo-hydrates and by being more or less successfully controlled by the same remedies; pathologically, they must still be regarded, in the absence of any demonstrable common determining cause, either functional or structural, as more or less distinct and specific diseases.

DR. J. T. DANA, of Portland, Maine, said that it seemed to him that this discussion might properly have been extended a little so as to include rheumatoid arthritis. In this affection he thought that the differentiation of it from the other affections has been well made out. He asked if this disease did not require correlation with the others considered?

DR. E. G. JANEWAY said that in considering the question of history we have to be careful in reading English writers. The English people all through are gouty. Any rheumatic tendency except in such individuals will not hold in other countries. We do not find the same correlation in America. His observation led him to believe that while members of the Hebrew race are very subject to diabetes, they do not have gout and rheumatism in the same proportion. With reference to the presence of albumen in the urine of diabetics, he had found that in many cases this was to be explained by the irritation of the urinary passages by the saccharine urine.

DR. A. L. LOOMIS, of New York, held that from a pathological standpoint we can not at present regard these diseases as directly, at least, correlated, yet from a clinical standpoint there are many things which make it difficult for us to divest ourselves of the idea that there is a correlation in rheumatism, gout, diabetes, and chronic Bright's disease. These

clinical phenomena are often so striking that one comes almost to regard these diseases as different manifestations of the same causes. He related the histories of some cases illustrating this point. The first was the case of a man of 63, who at the age of 42 had his first attack of gout. The urine was frequently examined at this period, and with negative results, presenting only a high specific gravity and nearly always an abundance of urates. In his 60th year, after a prolonged attack of gout, sugar appeared in the urine. From that time to the present he has not had an attack of gout. Sugar was presented until six months ago, when it disappeared, and now albumen is present. This change could not be accounted for by changes in habits or in diet. Two analogous cases were also reported. These cases are not unusual. It seemed to him that they compel us to take the position that while in their clinical phenomena they differ very markedly, still in their origin and development they seem to have many things in common; in other words, their correlation seems to be complete.

DR. H. C. WOOD had been led to conclude by his experience that gout and rheumatism were the same thing. He was unable to make the diagnosis between them. In the family of which he was a member the great grandfather was an Englishman and died of gout. The grandparents seem to have escaped, but the uncles and aunts almost without exception have died of gout. One brother has suffered with attacks of sub-acute rheumatism since the age of ten. Another brother has had six attacks of inflammatory rheumatism in as many years. Another brother went to the age of thirty years without any marked manifestation, when he had a severe attack of gout. Another brother has become almost a permanent cripple from inflammation of the muscles. He concluded it extraordinary if all this rheumatism and gout does not date back to one origin.

DR. WILLIAM PEPPER said that the clinical evidences of the correlation of these diseases seems to be so great that we cannot safely disregard it. In considering such common diseases, we must of course exclude mere coincidence. Dr. Draper has done well in calling attention to gout as a constitutional affection. If we confined ourselves to the mere arthritic phenomena we should exclude the great proportion of cases of gout as we meet with it in this country, which are perhaps as well included under the head lithæmia as anything else. He agreed with Dr. Janeway in regard to the frequency of diabetes in the Jewish race, but he had also found such persons very subject to lithæmia. In all these cases the importance which a diminution of vital resistance of any particular part plays in the development of the local manifestations, must be remembered.

Dr. Dana has referred to rheumatoid arthritis. This appears to be the form in which the nervous element is most marked. All have seen cases in which rheumatoid arthritis has been preceded by influences acting directly upon the nervous system. When we consider the immense amount of nerve force required in co-ordinating the digestive processes of the stomach, liver and kidneys, and in superintending the

metabolism in the tissues, it seems clear that a depressed condition of the nervous system must play a large part in the production of these affections. In studying cases of these diseases we are usually able to obtain a history of some cause of depression of the nervous system, and this affords a powerful argument in favor of the correlation between these diseases.

In regard to treatment, he could give evidence in favor of the salicylic acid treatment in certain groups of diabetics. These have been cases of the milder type associated with rheumatoid and arthritic phenomena. In one case the diabetes has been apparently cured, the patient having returned to the use of carbo-hydrates. In this case albumen still persists. The explanation of Dr. Janeway as to the cause of the albuminuria does not hold good in many of these cases. The disappearance of the sugar is not always accompanied by a corresponding decrease in the quantity of albumen.

DR. A. JACOBI, of New York, remarked that there was one form of rheumatism not so well known as the forms described, that is, the rheumatism nodosus sometimes seen in young subjects. This nodus form of rheumatism shows itself by the appearance of small lumps varying from half a dozen to several dozen, appearing not infrequently about the tendons of the fingers. He had seen them about the fascia, particularly of the head. Examination of these lumps show them to be composed of hypertrophied connective tissue.

In regard to the connection between diabetes and gout, there are several forms of diabetes. The form particularly connected with gout is that due to disturbances of the nutritive processes, particularly that of the liver. This is the form in which the salicylates do good. Their action seemed to him to be due to the influence of this drug over the liver in increasing the quantity of bile and in liquefying it. It is therefore a powerful agent in diminishing the tendency to the formation of gall stones. The forms of glycosuria which come and go are usually benefited by salicylate of sodium. This form of diabetes is generally found in anæmic persons, often very fat, and not infrequently among women of the Jewish race.

In reference to Bright's disease, this is quite common at the age of forty or fifty years, when atheroma of the small arteries appears. At that time gout is also common, and the co-existence of the two does not necessarily indicate a common causation.

DR. WM. H. DRAPER, in closing the discussion, said that in the cases of rheumatoid arthritis where a reliable history could be obtained, he had, as a rule, found evidences of a gouty origin, referring to gout in its larger significance. In regard to gout, he was strongly inclined to believe that the presence of uric acid is only an epi-phenomenon, and that its presence in the joints is not absolutely essential to the occurrence of other true gouty lesions. In the diabetes of Jews, he had seen the same association of lithæmic conditions as in other races.

He agreed with Dr. Wood in regard to the difficulties of diagnosis. The practitioner can not always satisfy himself whether he is dealing with gout or rheumatism. The correlation of these diseases is to

be made only from a clinical standpoint, and none can fail to recognize the frequent association of these diseases. Whether or not there is at the basis of all of them a similar pathological process is a question which has yet to be determined by pathological chemistry.

(To be concluded.)

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Statue of Sir Erasmus Wilson—Death of Dr. Francis Mason and Mr. Wm. White Cooper—Influence of the Mind on the Body—Statistics of Pneumonia—The Hydrophobia Commission.

A bronze statue of the late Sir Erasmus Wilson, erected in the grounds of the Royal Sea Bathing Infirmary, Margate, has been unveiled in the presence of a distinguished assemblage. The statue was erected by Mr. Brock, A.R.A., and was presented to the Infirmary by Sir James Paget on behalf of Lady Wilson. Among those present were Mr. Swinburne, the President of the Royal College of Surgeons, Dr. Oliver Wendell Holmes, Sir Spencer Wells, Sir Travers Lawrence, etc. Sir James Paget, in making the presentation, said no place seemed more appropriate for it than Margate, for close by was the home in which Sir Erasmus spent the later years of his life, planned many of his kind deeds, and in which he died in peace and in fair renown among all men. His studies had made him skilful in discerning external forms of disease, and especially those forms which were characteristic of diseases of the skin. In this branch of practice he soon prospered and made a large fortune. But though he became rich he made his income fairly. He never extorted money, he never grasped at it, he never took it from the poor, neither did he ever pretend to more knowledge than he believed he had. He did not scatter his money broadcast in small sums among the needy. He gave it to charities of which he observed the merit and the need, or to the promotion of that knowledge in which he had been chiefly occupied. He gave £10,000 to the Aberdeen University, a similar amount was given by him in order to have the Egyptian obelisk brought to England; towards the Sea Bathing Infirmary he subscribed £30,000, and during his lifetime he had given away no less a sum than £100,000. The statue was then unveiled amid much cheering. It is a faithful portraiture of Sir Erasmus, who is represented as wearing his Presidential robes.

Two well-known lights of the medical world have been removed by death. In his forty-ninth year Dr. Francis Mason, one of the senior surgeons of St. Thomas's Hospital, for many years associated with the late Sir William Fergusson, author of a work on "Hare-lip and Cleft Palate," and inventor of several surgical instruments; and Mr. William White Cooper, the eminent oculist, Surgeon Oculist in Ordinary to the Queen, whom he had attended for upwards of thirty years, and whose intention to confer a knight-

hood on him was only recently mentioned. Mr. Cooper was ophthalmic surgeon to several important institutions, and besides contributing largely to the literature of ophthalmology, was co-editor of Professor Owen's Hunterian Lectures on Comparative Anatomy.

At the last meeting of the Regent's Park Athenæum Society a paper on "The Influence of the Mind on the Body" was contributed by Dr. Howard Battey. Of all the mysterious processes of the mind he thought fear and faith exerted the greatest influence on the body. Fear predisposed to disease, while the simple exercise of faith had been known to produce wonderful and well authenticated cures. The influence of mesmerism had been quite established, but it was not advisable for medical men to import it into their practice, though the force might with advantage be employed in cases of nervous debility and sleeplessness. So-called hereditary consumption was often excited by nervous apprehension. In the course of the discussion which followed the reading of the paper Dr. Gutteridge, the chairman, said he had known cases of small-pox, scarlatina, and other infectious diseases originating solely through dread of the contagion. In one case a woman contracted small-pox by merely looking through a window at a passer-by who was suffering from the malady. Epidemics always subsided as soon as they could eliminate the element of fear.

A very good suggestion has been made by Mr. S. Yeldham of a plan for administering cod-liver oil to infants. He says: "Let the nurse dip the end of her little finger in the oil and put it into the child's mouth. This may be repeated five or six times in the twenty-four hours. In such small quantities, not only does it never disagree, but the child sucks it off the finger with avidity and evident pleasure. It may be administered in this way to the youngest infant." By this simple and inexpensive expedient, the writer says many infants, who were absolutely starving for want of natural foods, became fat and plump, and happily in an almost incredibly short space of time. The oil has the effect of enabling the child to digest other food which it could not retain on its stomach without it.

Dr. Angel Money has published some interesting statistics of pneumonia, with especial reference to the relations of delirium and temperature. The cases from which his deductions are drawn have occurred in University College Hospital during the past twelve years. From the author's investigations he had arrived at the same conclusions as Heinze had previously, viz.: that mere pyrexia had little to do in the production of delirium, but prolonged pyrexia and high transitory fever must exercise some direct and indirect deteriorating influence on the grey matter of the brain and spinal cord, and must therefore predispose to delirium and other signs of exhaustion of nervous matter. Of seventeen available cases, sometimes the delirium coincided with the greatest rise in temperature, rarely it preceded the acme of fever, and most frequently the delirium came on with the fall of temperature. Heinze drew attention to the much greater frequency of delirium or marked men-

tal change in pneumonia of the upper lobe. Taking additional precautions by employing only the cases in which the pneumonia was limited to the upper lobes, Dr. Money's observations confirmed this statement; and he suggested that the influence of a local inflammation on the cervical sympathetic, which controlled the calibre of the cephalic and cerebral vessels, might possibly have something to say in the matter. From an examination of other tables, it seemed clear that the presence or absence of delirium exerted no influence on the mortality. It seemed, however, that the third decade of life, when the temperature went beyond 104°, seemed to be the most fertile in the production of delirium; but it was pointed out that this age and this degree of fever yielded the largest number of cases of pneumonia.

A preliminary meeting of the Royal Commission appointed to report on M. Pasteur's method of preventing the development of hydrophobia in persons bitten by rabid dogs, was held recently at the house of Sir James Paget, in Hanover Square.

G. O. M.

DOMESTIC CORRESPONDENCE

THE ASSOCIATION OF AMERICAN PHYSICIANS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—The readers of THE JOURNAL will doubtless observe many familiar names in reading the proceedings of the first meeting of "The Association of American Physicians;" some who took an active part with the Original Committee of Seven of the American Medical Association in regard to the International Medical Congress to meet in this country in 1887, and some who took an active part against the Committee when it was enlarged. It may be asked, what means this multiplication of medical associations, and what is the necessity for them? In this case the answer is obvious. In reply I would answer the last question first—that there is apparently no necessity for them; and the reply to the first is, it means a bold and aggressive attack. The animus of this new association is open and apparent, for it is evidently organized ulteriorly in opposition to the American Medical Association, and is intended eventually, with kindred associations—the Surgical, the Gynecological, Laryngological, Ophthalmological, etc., to absorb that Association or destroy it, or its influence for usefulness, framing their organization in such a way as to keep out all who may be obnoxious to it in any way, and constituting *itself* the representative body of the medical profession in the United States. That seems to be the end in view.

But by what right can a hundred medical men or any other special number associate themselves together and call themselves "The Association of American Physicians? If they had called it "An Association of American Physicians," associated for a specific purpose, and limited to that object, it would not look so badly and no especial criticism or objection could be made against it, though exclusiveness against the spirit of science and its pursuit. Any

one has a right to be heard in prosecuting any of its branches, and no one can dictate to, or obstruct him in its development and promulgation. Knowledge is too widespread and its votaries are too numerous and universal to be hindered on their way in this period of the nineteenth century. But as this new association places itself before the public I do not hesitate to say that its projection is an insult to the rest of the medical profession in the United States, whose standing in every respect equals its members; and besides this, the character and intentions of this new association show a tendency to form a class relation which is altogether foreign to the intent and meaning of the Government under which we live.

But there is another aspect of the matter which comes home to the heart of every physician who regards the reputation of his country, in at least a practical point of view, as of paramount importance; and that is the strong contrast that will be attempted to be made between this new organization and the American Medical Association in the eyes of the medical world, especially in the eyes of our foreign medical brethren who may favor us with a visit at the International Medical Congress, and those also who decline to do so, because of the assumed distastefulness which it proposes to set up. Is the American Medical Association and the medical profession to be degraded by a set of men in its own ranks, in a profession which teaches and has always taught fraternity of feeling, and goodwill towards its fellows? Or do they intend to degrade themselves and their co-workers necessarily by breaking up the profession into little fragments, thereby producing such discord that the way may be opened to let in our enemies to destroy the traditions of medicine handed down to us through so many centuries. Can they be satisfied to sever the chain that has joined the far past with the present, and destroy the line and pathway by which medicine has reached its present eminence? And yet such seems to be the very object in view, and the animus of such organizations.

The day will come when such as seek to destroy the great temple of medicine in such ways—by caprice and whims and spitefulness—will wofully repent it, will abhor themselves sooner or later and be ashamed of their associates who, with themselves, lifted a hand or voice to aid in such nefarious work.

PRACTITIONER.

Washington, D. C., June 24, 1886.

BOOK REVIEWS.

A SYSTEM OF PRACTICAL MEDICINE. By American Authors. Edited by WILLIAM PEPPER, M.D., I.L.D., etc. Assisted by LOUIS STARR, M.D., etc. Volume IV. Diseases of the Genito-Urinary and Cutaneous Systems—Medical Ophthalmology and Otology. 34 Illustrations. 8vo., pp. 877. Philadelphia: Lea Brothers & Co. 1886.

The great "System of Medicine," ably edited by Dr. Pepper, and so ably written by his colleagues, is now almost completed; within a short time the fifth

and last volume will be before the public. If the fifth volume be as well written as the first four surely the highest expectations of the editor and his colleagues will be more than realized.

The two chapters on "Diseases of the Kidneys" are contributed by Dr. Robert T. Edes, of Boston, and Dr. Francis Delafield, of New York. Dr. James Tyson then contributes two chapters on "Hæmaturia and Hæmatinuria, and on Chyluria." These, with two chapters on "Diseases of the Male Bladder," by Dr. Keyes, and on "Seminal Incontinence," by Dr. S. W. Gross, bring us to the gynecological portion of the volume, which includes chapters on "Displacements of the Uterus," by Dr. E. C. Dudley, of Chicago, "Disorders of the Uterine Functions, including Amenorrhœa, Dysmenorrhœa, and Menorrhagia," by J. C. Reeve, M.D., "Inflammation of the Pelvic Cellular Tissue and Pelvic Peritoneum," by Dr. B. F. Baer, of Philadelphia, "Pelvic Hæmatocele," by Dr. Thomas, "Fibrous Tumors of the Uterus," "Sarcoma of the Uterus," and "Carcinoma or Cancer of the Uterus," by Dr. W. H. Byford, "Diseases of the Ovaries and Oviducts," by Dr. Goodell, "Diseases of the Urinary Organs in Women," by Dr. A. J. C. Skene, "Diseases of the Vagina and Vulva," by Dr. Edward W. Jenks, of Detroit, "Disorders of Pregnancy," by Dr. W. W. Jaggard, of Chicago, who also contributes the articles on "Functional Disorders in Connection with the Menopause," and "Diseases of the Parenchyma of the Uterus; Metritis and Endometritis, including Leucorrhœa," and "Abortion," by Dr. George J. Engelmann, of St. Louis.

It might seem invidious to select any of the gynecological articles and say that it is the best; but it is particularly noticeable that the articles written by the younger authors are not less readable or valuable than those by writers of wider reputation; and certainly one could not wish better articles than those on "Disorders of Pregnancy," and "Abortion."

"Diseases of the Muscular System" are included in this volume, though more properly belonging to nervous diseases. Under this head are three articles, "Myalgia," by Dr. James C. Wilson, of Philadelphia, "Progressive Muscular Atrophy," by Dr. Tyson, and "Pseudo-hypertrophic Paralysis," by Mary Putnam Jacobi, M.D. The section on "Diseases of the Skin" is written by Dr. Duhring and Dr. Stelwagon, of Philadelphia, that on "Medical Ophthalmology," by Dr. Wm. F. Norris, of Philadelphia, and that on "Medical Otology" by Dr. George Strawbridge, of Philadelphia.

It is a noticeable and somewhat remarkable fact that six of twenty-one contributors to this volume are residents of the West; a fact which seems to show that while some of his *confrères* assert that all the medical talent of the country is confined to Philadelphia (and New York and Boston by courtesy), the Editor of the "American System" does not quite believe it.

A MANUAL OF SURGERY. In Treatises by Various Authors. In three volumes edited by FREDERICK TREVES, F. R. C. S., Surgeon to and Lecturer on Anatomy at the London Hospital. Volume I,

General Surgical Affections, The Blood-vessels, The Nerves, The Skin. Vol. II, The Thorax, The Organs of Digestion, The Genito-Urinary Organs. Vol. III, The Organs of Locomotion and of Special Sense, The Respiratory Passages, The Head, The Spine. Duodecimos, 1866 pages, 213 engravings. Per volume, cloth, \$2. Philadelphia: Lea Brothers & Co. 1886. Chicago: A. C. McClurg & Co.

The three volumes of which this Manual is composed are concerned mainly with the clinical, diagnostic, and therapeutic aspects of surgery. The general principles of operative surgery are dealt with, but the technical details of the various procedures are omitted, with the exception of such as concern what may be termed special operations, as tracheotomy, gastrotomy, nephrectomy, ovariectomy and the like. Pathology is discussed only in so far as it directly affects the clinical phases and the intelligent treatment of disease.

The editor of this Manual, though young, has made a name for himself as a surgeon of rare ability, and when one finds connected with his name those of John Chiene, A. J. Pepper, Malcolm Morris, Mansell Moullin, Pearce Gould, Frederick Eve, H. T. Butlin, John Duncan, Jonathan Hutchinson, Herbert W. Page, Greig Smith, Mitchell Banks, Harrison Cripps, Sir William MacCormac, Fourniaux Jordan, and others, he must feel convinced at the outset that though the work may be small it represents the best surgical knowledge of England, and will be a welcome addition to the library of the American surgeon. Each volume is indexed separately.

A COMPEND OF PHARMACY. By F. E. STEWART, M.D., Ph.G., Lecturer on, and Demonstrator of Pharmacology in the Medico-Chirurgical College of Philadelphia, etc., etc. Based upon Prof. Joseph P. Remington's "Text-book of Pharmacy." Sm. 8vo., pp. viii—196. Philadelphia: P. Blakiston, Son & Co. 1886. Chicago: W. T. Keener.

This book is No 11 of the Quiz-compend series, issued by the publisher. It shows evidence of great care in its preparation, and will be of service not only to the student, but to the recent graduate in Pharmacy, and to the physician who has to prepare his own drugs or prescriptions. It contains a list of officinal preparations, and lists of the preparations of the inorganic and organic materia medica, with directions.

MISCELLANEOUS.

PREVENTIVE INOCULATION IN YELLOW FEVER.—The subject of inoculation for yellow fever, as practised by Dr. Domingos Freire, of Rio de Janeiro, was brought under the Société de Biologie of Paris at its last meeting. M. Rebourgeon communicated the results obtained by himself and Dr. Freire in December, 1885, and January and February, 1886. The weather during these months in Brazil was intensely

hot, and yellow fever prevailed severely. Of 3051 subjects inoculated at Rio not one had died, whereas in the same districts and houses 278 non-vaccinated had succumbed to the disease. The number of the inoculated has now reached 6000, and not one of them has been attacked with the fever; and, what is more remarkable, severe cases inoculated in the second stage of the disease had all recovered. In reply to M. Brown-Séquard, M. Rebourgeon said that but few foreigners were inoculated, but yellow fever is at the present time creating great ravages among the Brazilians and mulattoes; the negroes even are being largely attacked, which is a rare occurrence; and the area of the disease was extending inland from the littoral. He explained that some specimens of virus sent two years ago to M. Cornil, and found by him to be worthless, had not been sent by Dr. Freire, but by opponents to his method. He had often inoculated himself, and was so convinced of the efficacy of the attenuated virus that he had frequently offered to undergo inoculation with the yellow fever itself. He presented a specimen of the vaccine to the Society for examination. In reply to M. Maurel, he said that he had met with yellow fever at an altitude of more than 700 metres, and had seen many cases among emancipated negroes, although less than among mulattoes, who were attacked in about the same proportion as the whites. M. Maurel attributed the former immunity of negroes to their vegetable diet, but since emancipation negroes had largely adopted the customs of the whites and consumed more animal food. A commission to study the method of inoculation was appointed, consisting of MM. Brown-Séquard, Cornil, Duval, Bourquelot, and Maurel.—*Lancet*, June 5, 1886.

MISSISSIPPI VALLEY (FORMERLY TRI-STATE) MEDICAL SOCIETY.—The annual meeting will be held at Quincy, Ill., July 13, 14 and 15, 1886, at 10 A.M. Those in attendance will be returned over the railroads centering in Quincy for one-third fare, on the certificate of the Secretary of the Society; but to secure this reduction each person, on buying his ticket to Quincy, *must take the receipt of the local ticket agent for "full fare" over the roads named on the ticket.*

This is not a delegate society, but admits to membership—simply by registration—all practitioners in good and regular standing who may attend its meetings and wish to affiliate with it. A cordial invitation to be present is extended to all members of the profession.

JOSEPH ROBBINS, M.D.,
Chairman Com. of Arrangements.

THE INTERNATIONAL CONGRESS OF PSYCHIATRY AND NEUROLOGY, AND MR. CLARK BELL.—At a meeting of "The Society of Medical Jurisprudence and State Medicine, held at the Academy of Medicine, 12 West 31st Street, New York City, April 8th, 1886, the following preamble and resolutions were unanimously adopted:

WHEREAS: It appears from the minutes of the New York Neurological Society, that Clark Bell, Esq., sent a communication to an officer of that body,

which was submitted to the council of officers of the same body and by them to the Society; and

WHEREAS: The said Clark Bell, Esq., in the aforesaid communication represented that he acted as the American delegate of the International Congress of Psychiatry and Neuro-Pathology, the function of said International Congress of Psychiatry and Neuro-Pathology at Antwerp, being the selection of a proper classification of those disorders collectively designated as insanity; and

WHEREAS: All the European collaborators on this worthy undertaking are experienced alienists of high scientific repute, teachers at Universities or physicians engaged in the special treatment of nervous diseases; and

WHEREAS: The said Clark Bell, Esq., is singularly the only North American represented in the same undertaking; and

WHEREAS: It is highly desirable that the important branch of medical science, known as Psychiatry, which above all others is of common interest to the medical and legal professions, should, on so important an occasion as the international classification of its intricate subject matter, be represented worthily; and

WHEREAS: The said Clark Bell, Esq., is not an alienist, not even a physician; and

WHEREAS: As far as eminent Neurologists, members of our Society, have been able to learn, no body of specialists engaged in the study of nervous diseases has any knowledge of the reasons for the appointment of said Clark Bell, Esq., on the commission of said body, or on what representations it was obtained; therefore, be it

Resolved, That the Corresponding Secretary of the Society of Medical Jurisprudence and State Medicine, be instructed to forward the following, as well as the preamble, to the President and Secretary of the International Congress of Psychiatry and Neurology, as well as the physicians of the Commission empowered to prepare a classification of mental diseases.

Resolved, That the Society of Medical Jurisprudence and State Medicine expresses its surprise that the first time the important subject of the Classification of Insanity becomes the subject of international consideration, a subject which, however, interesting to both lawyers and physicians, is pre-eminently and exclusively a question of medical science, it should have been seen fit to entrust the representation of the entire North America to one who is not a qualified practitioner of medicine; and

Resolved, That the International Congress of Psychiatry and Neuro-Pathology at Antwerp, be respectfully requested to duly weigh the considerations above advanced; inasmuch, as if it be worth the while to have American Medicine represented in the important undertaking referred to, it is worth the while to have it represented by some one or several of those who are pre-eminent as original contributors to that science in whose annals the names of Benjamin Rush, Luther Bell, Isaac Ray, Pliny Earle, and W. W. Godding, are almost household words.

Resolved, That the International Congress of Psychiatry and Neuro-Pathology at Antwerp, be respectfully referred to the American Neurological As-

sociation, the New England Medico-Psychological Society, and similar bodies whose history and membership may be referred to with just pride by American physicians as bodies which might be safely depended upon to select worthy representatives in the important undertaking of classifying disorders which are pre-eminently the study of medical men.

FRANK H. HAMILTON, A.M., M.D., L.L.D.,
President of the Society of Medical Jurisprudence and State Medicine.

WM. M. MCILAURY, M.D.,
President of the Board of Trustees of the Society of Medical Jurisprudence and State Medicine.

GEORGE W. WELLS, M.D.,
Recording Secretary of the Society of Medical Jurisprudence and State Medicine.

JEAN F. CHAUVEAU, M.D.,
Corresponding Secretary of the Society of Medical Jurisprudence and State Medicine.

INDIANA STATE MEDICAL SOCIETY.—At the recent annual meeting of this Society, the following officers were elected for the ensuing year:

President, G. W. H. Kemper, M.D., of Muncie.

Vice-President, W. V. Wiles, M.D., Spencer.

Secretary, E. S. Elder, M.D., Indianapolis.

Assistant Secretary, J. McLean Moulder, M.D., Kokomo.

Treasurer, C. B. Higgins, M.D., Peru.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 19, 1886, TO JUNE 25, 1886.

Col. Glover Perin, Asst. Surgeon-General U. S. Army, granted leave of absence for one month, with permission to apply for one month's extension. (S. O. 54, Dept. Dak., June 14, 1886.)

Major John Brooke, Surgeon, ordered for duty as Post Surgeon, Ft. McHenry, Baltimore, Md. (S. O. 67, Div. Atlantic, June 23, 1886.)

Major Calvin DeWitt, Surgeon, ordered for duty in Dept. Dakota. (S. O. 142, A. G. O., June 21, 1886.)

Capt. Jno. de B. W. Gardiner, Asst. Surgeon, ordered for duty as Post Surgeon, Newport Bks., Newport, Ky. (S. O. 67, Div. Atlantic, June 23, 1886.)

Capt. Robert J. Gibson, Asst. Surgeon, granted leave of absence for thirty-five days. (S. O. 43, Div. Pacific, June 14, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JUNE 26, 1886.

Beardsley, Grove S., Medical Inspector, detached from the Navy Yard, Norfolk, and ordered to the "Brooklyn."

Bright, G. A., Surgeon, detached from "Brooklyn" and ordered to Navy Yard, Norfolk.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED JUNE 26, 1886.

Sawtelle, H. W., Surgeon, to proceed to Wilmington, Cal., on special duty. June 22, 1886.

Wheeler, W. A., P. A. Surgeon, granted leave of absence for thirty days. June 23, 1886.

Williams, L. L., Asst. Surgeon, to proceed to Buffalo, N. Y., for temporary duty. June 24, 1886.

Norman, Seaton, Asst. Surgeon, to proceed to Cleveland, Ohio, for temporary duty. June 26, 1886.

CORRIGENDUM.

DILATATION IN UTERINE FLEXIONS.—In THE JOURNAL of June 26, p. 271, first column, Dr. H. T. Byford is reported as saying: "I congratulate Dr. Jackson that he has discarded incision and dilatation in treating flexions." Dr. Byford writes us: "The word *dilatation* should read *dissection*. I believe in dilatation, and think it one of our most valuable resources for flexure and induration in the neighborhood of the internal os."

ADDRESS

IN DENTAL AND ORAL SURGERY.

Delivered at the Thirty-Seventh Annual Meeting of the American Medical Association.

BY JOHN S. MARSHALL, M.D.,

OF CHICAGO, ILL.

One of the duties of a Chairman of a Section is to examine, sift, and weigh the material that has accumulated during the year in relation to the department of medicine over which he may preside in this Association, and which may have more or less legitimate claims upon the profession as new discoveries, new theories, or improvements in methods of operating, or treatment, and to bring to your notice such of them as are in his judgment of greatest importance. This I have found to be by no means an easy task. My report, however, will be brief.

TRANSPLANTATION OF TEETH.

Let me first call your attention to a matter which has somewhat startled the scientific world, and particularly that portion of it interested in dental and oral surgery, viz.: the discovery made by W. J. Younger, M.D., of San Francisco, California, that teeth can be transplanted into artificial sockets drilled in the jaws, and apparently, made to unite with the surrounding tissues as firmly as though placed there by the natural process of dentition.

The operation of transplanting teeth from the mouth of one individual into the natural alveoli of another was first performed by John Hunter, but it soon fell into disrepute from the annoyances and dangers which so often followed it, among which may be mentioned immediate suppurative inflammation, which prevented the union of the tooth with the alveolus; subsequent alveolar abscess, the result of the putrefaction of the pulp; necrosis of the jaw, and occasionally tetanus.

The revival of this operation, and the introduction of *replanting* teeth as a curative measure for alveolar abscess, under antiseptic precautions, a decade or more ago, viz.: the extirpation of the pulp, the filling of the pulp canal, and the washing of the tooth and alveolus with some one of the antiseptic preparations, has placed it among the successful operations, so far as the immediate annoyances and dangers before mentioned are concerned. But the operation really cannot be called successful even in those cases where firm union has taken place, for in very many of them, sooner or later, resorption of the root occurs

similar to if not identical with that phenomenon which takes place in the process of shedding the deciduous teeth, and the tooth becomes loose, and either drops out or has to be extracted. The failures in the operation of transplanting have been variously estimated at from 25 to 50 per cent., but when we take into consideration the fact that very many of the teeth thus treated fail after a year or two of union, the percentage must be very much higher.

Quoting from the *Pacific Medical and Surgical Journal and Western Lancet*, January, 1886, Dr. Younger says: "*But transplantation can be made a success and void of all danger and unpleasant consequences, if only common sense, cleanliness, and ordinary skill and care are taken.*" And it is to prove this and unprejudice the scientific mind, and through it the public, and do away with the abomination of false teeth, that he "presents to the profession the results of his experiments and experience in this direction.

"He gained courage to try the operation by reflecting on the experiment of John Hunter, who to test the vitality of the pericementum, planted a tooth in a cock's comb. This tooth attached itself firmly to the crest, and a few months afterwards the cock was killed and microscopical examination showed that a living union had taken place, the blood-vessels of the comb and pericementum having established free communications."

Dr. Younger "also tried the experiment upon a cock's comb, to further and personally assure himself of the truth of this statement, and confirmed, as far as attachment was concerned, the experiment of the great surgeon. But in his experiment, he took the precaution of removing the pulp and filling the pulp chamber and root canal with a preparation of gutta percha much used by dentists for temporary fillings. This was in order to avoid any trouble from a decomposing pulp. The tooth was then well cleansed with warm water and dipped in a disinfecting solution.

"The success of this experiment satisfied him that the pericementum would attach itself to any vascular body, and that if properly planted in a fresh socket it would attach itself and form a living union with the surrounding tissues, without the production of after-pains or other evil consequences."

The first practical experiment upon the human subject of transplanting a tooth into a natural alveolus performed by Dr. Younger was on January 24, 1881. The tooth was treated in the same manner as that described for transplantation in the comb of the cock: the alveolus was washed out with a disinfecting

solution, the apex of the root trimmed to make it of the desired length, and then pressed into position, and retained by delicate silk ligatures attached to adjoining teeth. At the end of four weeks the ligatures were removed and the tooth found to be firmly attached to the surrounding walls of the alveolus, and at the time of writing his paper, was still doing good service.

Dr. Younger reports "between thirty and forty cases of transplanting into sockets already formed"—natural sockets—with "but two failures;" one due to the neglect of the patient, and one to his own inexperience. These are remarkably good results, so far as they go, but a sufficient length of time has not yet elapsed to prove them permanently successful, for resorption of the roots may yet take place and the teeth be lost. This has been the experience of many of the most careful and painstaking operators, and I shall be greatly surprised if in some of Dr. Younger's cases which now appear to be successful, this does not prove to be the final outcome.

Thus far in the experiments of Dr. Younger, he has traveled over the same ground previously traversed by many others of his professional brethren, but from this point he enters a new and entirely unexplored field, and first introduces the novelty of making a garden or nursery of a cock's comb in which he plants freshly extracted teeth, and thus retains their pericemental vitality for an indefinite period, or until such time as a favorable opportunity presents to transplant them into the human mouth. Let me quote him upon this point. He says: "The great and only difficulty I had to contend with was the procurement of teeth at the time they were needed. At last a way suggested itself. I applied to my dental friends for whatever good teeth or roots the exigencies of cases required them to extract. The experiment of Hunter and my own experience had taught me that teeth could be kept alive, indefinitely, in cocks' combs. But could they be transplanted to the human mouth again and made to grow there? I concluded they could, and my first experiment verified my conclusion. On November 28, 1885, a bicuspid that had been in a cock's comb for ten days was transferred to the mouth of a gentleman, where it fastened itself, as if there had been no gallinaceous period in its existence.

"Where he has not been able to procure a suitable tooth, he has taken a root and mounted an artificial crown upon it. Sometimes he used the natural crown of a tooth that had been irretrievably loosened by incrustations of tartar on its roots. In this case he simply saws off the bad root and attaches a good one to its crown by means of one or more gold screws and cement. In these cases the patient simply changes roots. He says: I have also discovered that the pericementum can be kept alive for certainly two days in warm water, temperature 100° to 110° F. He has in two cases transplanted teeth successfully that had been so kept for fifty hours."

He next describes how he was led to the discovery of the fact that teeth can be transplanted into *artificial alveoli* drilled in the bones of the jaws, and made to unite with the surrounding bony tissues and the

gum. "His former practice, when he found a root was too long or too wide for the socket, was to cut off from the apical extremity, or shave off from the surface of the root, the necessary quantity to insure a fit; but so often the best portion of the pericementum was in that way removed, that he tried deepening or widening the cavity as the case required, often cutting freely into the bone in order to save all possible of this valuable pericemental tissue. And he found that adhesion took place in this portion as perfectly as in the unbroached. The consideration of this led him to the grand conclusion that artificial sockets could be drilled into the bone itself and teeth planted therein as successfully as into the natural cavities."

The first operation of this kind was performed upon a young lady on June 17, 1885, and up to the month of January of the present year he reports having made the operation *seven* times in all. "Four teeth were transplanted in the mouth of one patient, and one each in three others, the original teeth having been lost for periods varying from two to twenty years. All of these are reported as entirely successful, no serious after-trouble following the operation, and the union is perfect with the jaw and the gum."

The first operation, which is a fair sample of all the others, is described as follows: "Miss W., a young lady of 24 years, had lost the left superior lateral incisor, root and all, four years previously, and had been wearing as a substitute an artificial tooth on a rubber plate. The collapse of the gum, consequent on the absorption of the alveolus, was so great, and the exposure of (artificial) gum so much, in conversation, and especially in smiling, that the falsity of the denture was immediately recognized, and was an object of great distress to her. As it was impossible, for the reasons just given, to produce an artificial substitute that would look natural, he determined upon the following operation: Taking a corresponding lateral from the mouth of a young man, which, from its awkward position, was disfiguring his appearance, he prepared it as he does all teeth used in transplantation, viz.: removed the pulp, filled the pulp chamber and root canal with Hill's stopping, and finished the apex with gold. The tooth was then placed in water of the temperature of 100° to 110° F., to cleanse it of all blood and impurities, and allowed to remain about one hour. It was then placed in a bath of bichloride of mercury, 2 parts to 1,000 of water, for about fifteen minutes, to disinfect it. The tooth being now ready, attention was turned to the patient. A hole was cut in the gum a little less than the diameter of the root to be inserted. He then took an ordinary flat, angular-edged drill, and drilled into the bone in the line of direction the tooth was to occupy. When fully deep enough, the cavity was widened and the socket formed with a cone-shaped burr. When it was found by trial that the cavity would receive the tooth perfectly, it was carefully washed and sponged, in order to remove every particle of detached bone, first with warm water, then with cold, and lastly with the bichloride solution already referred to, and when the bleeding had ceased, the tooth was introduced and kept in position by delicate silk ligatures attached to the central incisor on the right and

the canine on the left. There resulted a little swelling over the root, which remained a few days and then gradually disappeared. An accident occurred to the gum during the development of its socket. Just as the drill touched the surface of the bone, the young lady suddenly moved her head, which caused the instrument to slip forward and through the gum, making a triangular-shaped gash of fully an eighth of an inch in length. Before the tooth was inserted, the edges of this wound were brought carefully together and retained in contact by delicate silk sutures. On the fourth day the sutures were removed and no mark was apparent to tell of the lesion that had existed. In twelve days the ligatures were removed from the tooth and it was found to be well attached. About three weeks afterwards, the gum being free from any sign of irritation and the tooth comparatively firm, and as it was desirable to improve the position of the right superior central and lateral, ligatures were passed around the new tooth. This, unfortunately, set up a slight inflammatory action, and an abscess formed a few days after, and a little discharge of pus took place. The ligatures were immediately removed and the abscess treated with injections of iodine. And he says: When last seen the abscess had entirely disappeared, the surrounding gum had resumed its normal appearance, the tooth became firm in its position, and is now performing its functions in common with its fellows as though it had never been a stranger in the mouth." Dr. Younger publishes the names of several medical gentlemen, some of them members of this Association, I believe, and also the names of several dental practitioners known to the profession, who have examined these cases in a critical manner and have expressed themselves as "fully satisfied with the success and utility of this operation."

In an addendum to his paper Dr. Younger offers an explanation of the process of union, which takes place in this class of cases between the tooth and the bone into which it is placed. These views may be briefly summarized as follows: The dental alveolus has no periosteal lining, and the pericemental membrane which covers the root of the tooth—be it a single or double membrane—"has a callus generative energy" only upon that side in contact with the tooth, while the outer surface "has simply the power of forming attachment." To the *endosteum* which lines the cells and interstices of the surrounding bony tissue, he believes belongs the power of forming the alveolus about the tooth, whether the tooth is erupted by the physiological process of dentition, or artificially implanted.

To prove this theory he proposes to commence (for publication) a series of experiments upon rabbits, by drilling into various parts of their osseous tissue, and implanting roots of teeth into these cavities, and then at various intervals to kill the rabbits and make critical microscopical examinations of the existing conditions of the implanted roots and the surrounding bony structure.

Of the immediate success of Dr. Younger's operations there cannot be a shadow of doubt, for the evidence is supported by unimpeachable witnesses. But the permanent success of the operation is not

yet assured. It will require a much larger number of operations to establish its practicability, and several years to prove it permanently successful. It is to be feared that the same causes which have operated against the permanent stability and usefulness of so many teeth replanted and transplanted into *natural* alveoli, would operate against those teeth transplanted into artificial sockets, and would therefore advise that we "make haste slowly" in adopting so radical and startling an operation; but I trust these fears may prove entirely unfounded, and that the introduction of this operation may, as Dr. Younger hopes, "do away with the necessity for false teeth, and so add immeasurably to the comfort, beauty and health of the human mouth."

Next let me call your attention to the operation of

SPONGE-GRAFTING IN THE MOUTH.

This subject of sponge-grafting has for the last two or three years been receiving considerable attention by way of experimentation from specialists in dental and oral surgery; but operations in the direction of restoring lost tissue in the mouth by this means, have until lately met with very limited success. During the last year much better results have been obtained, consequent largely upon the improved methods in preparing the sponge, in protecting it against septic influences after being placed in position, and in lessening its liability to become displaced. Much greater difficulties have to be overcome in using the sponge-graft in the mouth than upon the external surfaces of the body. In the latter the usual antiseptic dressings are all that are needed to protect the sponge and wound from the entrance of micro-organisms, and to retain it in position; while in the former no such dressings can be employed, as they immediately become saturated with the oral secretions and fouled by the introduction of food into the mouth. The sponge also needs to be prepared in such a manner as to render it as nearly *permanently* antiseptic as possible, for the reasons just mentioned.

The method generally followed in preparing the sponge for grafting is that introduced by Dr. Edward Borck, of St. Louis, viz.: to remove all the earthy matter that might be contained in the sponge by placing it in dilute hydrochloric acid, and then, after washing it, to render it antiseptic by treating it in iodoform dissolved in sulph. ether, the sponges afterwards to be dried and excluded from the air by being placed in tightly corked bottles. Sponges, however, prepared in this manner, if kept for any length of time shriveled, became soft, and soon disintegrated thus rendering them useless, and making it necessary to prepare a fresh sponge for each case.

To Dr. Wm. H. Atkinson,¹ of New York, belongs the credit of suggesting an improvement in the preparation of the sponges and in the means of retaining the graft in position. He says "choose fine surgeons' sponges, free them from foreign elements," and then place in a "sterilizing solution made by adding one grain of bi-chloride of mercury to one oz. of distilled water," and then raise the temperature to 130° F. and maintain it at that degree for from ten

¹ "Transactions American Dental Association," 1885, p. 149.

to thirty minutes. He adds a word of caution in regard to the heating of the sponges, for if the temperature is allowed to go much above 130° the sponge is likely to be spoiled, for albumen begins to coagulate at 133° , and is cooked if it gets beyond 163° to 164° , and is then "not fit to be wrought into tissue." Sponges treated by this method can be kept for an indefinite period if placed in the above sterilizing fluid and excluded from the atmosphere.

The methods which he suggests for protecting sponge-grafts in the mouth from the dangers of being displaced by mastication or in cleansing the teeth, etc., is to form a splint from thin platinum plate, which shall cover the parts and be closely adapted, and at the same time free from pressure over the graft.

The class of operations in which Dr. Atkinson has been most successful, are closing the pus-pockets resulting from pyorrhea alveolaris, the reproduction of lost alveolar and gum tissue, and the healing of chronic alveolar abscesses.

Few operations in the mouth outside of these just mentioned, have yet been attempted, but there is every reason to believe that with care and skill, perforations of the hard and soft palates, the result of surgical operations, injuries, or specific disease may be successfully closed by it, and lost parts in other locations of the mouth and face, more or less completely restored by the same means.

The success of the operation, however, when made in the mouth will depend very largely upon our ability to prevent the contamination of the sponge with septic organisms. This in most cases may be accomplished by frequently and freely washing the parts with peroxide of hydrogen, followed by the bichloride solution, 1 in 1000.

Finally, allow me to direct your attention to the

OPERATION FOR HARE-LIP AND CLEFT PALATE

in early infancy, as performed and strongly advocated by Dr. D. H. Goodwillie, of New York. In these cases there has been a failure of union during inter-uterine development between the maxillæ and the lateral halves of the lip, and a cleft is the result. In this condition the anatomical relations of the parts are changed, both in form and dimensions. The maxillæ now separated cause an abnormal increase in their dimensions, and when extended forward producing a single or double hare-lip, there is also great distortion of the face.

Dr. Goodwillie's method is to replace the separated and distorted maxillæ and nose to their normal relations by *manual force* repeatedly applied. But in order to accomplish this with the least difficulty, it must be done as soon after birth as the conditions and circumstances surrounding the child will permit, and before ossification has had time to advance. When the bony frame-work has been restored to its anatomical position, then the operation on the cleft lip and soft palate should immediately follow. For the operation of staphylorrhaphy and uranoplasty the child is etherized and confined in a metallic jacket and head rest. The patient is then placed in a good light, and in such a position that the surgeon stand-

ing with the head of the patient against his breast, can, by looking over, command a full view of all parts of the palate. The arms of the operator rest upon the head of the patient and thus enable him to control his movements. The oral speculum is then placed in position and the assistant holds down the tongue by means of a hollow tongue-holder and etherizer combined, through which anæsthesia is maintained during the operation. This is a very great advantage, as it saves valuable time, which is otherwise lost by frequent halts in the operation to reapply the anæsthetic.

The divided uvula is then seized with the forceps, and with the small pointed knife the edges of the cleft are pared from the uvula forward to the anterior point of the cleft. The ligatures are then passed, beginning at the posterior part of the cleft, by means of a hollow needle and holder, armed with silk-worm gut; the point of the ligature is then pushed through the needle and grasped by the forceps and the needle withdrawn. The ends of the ligature are secured temporarily by means of small leaden clamps; this is repeated until the required number are passed. The ligatures are afterwards tied with the fingers, commencing, as a rule, with the posterior one.

If any point appears to be unduly strained by the ligature, a suture-pin clamp is adjusted to relieve the tension upon the sutures and is allowed to remain until union has taken place. The methods of dividing the levator palati and palato-pharyngeal muscles as those in common practice.

In uranoplasty, the soft tissue covering the hard palate is either lifted from the bone by means of periosteal elevators, or lateral incisions are made through the soft tissue and the bone drilled and split, and afterwards brought together and held in position by ligatures and clamps, which are permitted to remain for from six to twelve days.

To prevent the child from getting the hands to the mouth, leather elbow-pads are strapped upon the arms.

The instruments used for these operations by Dr. Goodwillie are of his own designing, and meet a long-felt want on the part of oral surgeons, and convert an otherwise tedious and disagreeable operation into one of comparatively slight inconvenience.

THE VALUE OF THE KNEE-PHENOMENON IN THE DIAGNOSIS OF DISEASES OF THE NERVOUS SYSTEM.¹

BY PHILIP ZENNER, A.M., M.D.,

LECTURER ON DISEASES OF THE NERVOUS SYSTEM IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

Since the simultaneous publications of Erb¹ and Westphal,² in 1875, on this subject, the knee-phenomenon has attracted a great deal of attention on

¹ Read before the Medical Section of the American Medical Association, May 5th, 1886.

² Archiv. Psych. und Nervenkrankheiten, V, 792.

³ Ibid., 803.

the part of the profession, both as to its nature and its clinical significance. Erb termed the phenomenon the patellar-tendon reflex; Westphal the knee-phenomenon; while the English usually speak of it as the knee-jerk. Each of these terms is in common use, signifying alike the contraction of the quadriceps femoris muscle and the forward jerk of the foot, when a sharp blow is struck upon the *ligamentum patellæ*.

The question of the nature of this phenomenon need not detain us long. The views originally expressed by Erb and Westphal still divide the opinions of the profession. Erb believes it to be true reflex action, a peripheral impression being conveyed to the centre in the spinal cord, and thence a motor impulse transmitted to the muscle. Westphal believes that the contraction of the muscle is due to the direct irritation of its fibres, caused by their sudden stretching, the spinal cord having no cognizance of the act. He believes, at the same time, that certain conditions of the muscle and tendon are necessary; that is, a degree of muscular tonus, and a certain tension of the muscle and tendon, as well as a capability of free vibration of the tendon. The muscular tonus is maintained, in a reflex way, by the cord. The phenomenon is, therefore, affected by the condition of the cord, though it is not a true reflex act.

I will not occupy your time by giving the argument *pro* and *con* for either of these views. Neither can be said to be fully established, but that of Westphal appears to find most adherents at the present time. In either case it is true that, for a normal appearance of the phenomenon, a normal condition of the spinal centres and of the nerves emanating from them is necessary. Destruction of the lumbar portion of the cord, or of the nerves leading to or from it, will abolish the phenomenon.

The phenomenon gained its clinical significance when Westphal pointed out, as he did in his first publication, that it could be elicited in health, and that it was always absent in typical cases of locomotor ataxia. Its great diagnostic value is attached to the fact of its early disappearance in this disease, being, probably, often the first sign of disease. The phenomenon may also be abolished in anterior poliomyelitis, affecting the lumbar portion of the cord, and in neuritis, when the nerves issuing from the same part are affected, for in such instances the reflex loop is impaired upon whose integrity the normal manifestation of the phenomenon depends. It is also frequently abolished in cases of diabetes mellitus, and has been found temporarily absent in chronic alcoholism and subsequent to attacks of diphtheria.

Is its absence always of pathological import? The investigations which have been made to determine this question have differed considerably in their results. Berger examined 1409 healthy persons, including 900 soldiers, and failed to elicit the phenomenon in 22, or 1.56 per cent. of the cases. Eulenberg found it absent in 4.8 per cent. of healthy adults examined by him, and in over 5 per cent. of children. Bloch* examined 694 school children and found it absent in five of them. While these figures represent the phenomena as absent in a small, but still

respectable, number of apparently healthy persons, Pelizaens⁴ examined 2403 school children, and though he failed to elicit the phenomenon at first in six, finally succeeded in eliciting it in all but one, in whom it was subsequently obtained by a special manner of examination;⁵ and Jendrassik⁶ examined 1000 persons, chiefly adults, with no manifest disease of the nervous system, and only failed to elicit the phenomenon in a single person, that being a case of diabetes mellitus.

In view of the considerable difference of the results of these various observers, I have deemed the matter of sufficient importance to institute further examination in this direction, the report of which is embodied in this paper. Not all the persons were examined by myself; many were examined by medical friends at my request, especially the insane cases. For the latter I am indebted to Dr. Richardson, of the Athens Asylum, Drs. Clara M. Ellsbury, Frank B. Wynn, and Crumley, of the Dayton Asylum, Dr. F. W. Harmon, of Longview Asylum, and Dr. O. Everts, of the Cincinnati Sanitarium. But in all instances, excepting those at Athens and two other insane subjects, I examined personally the individuals in whom the phenomenon was said to be absent.

The whole number examined was 2106, of whom all were adults. Of these, 1174 were inmates of insane asylums. Of the 932 remaining, 100 were patients in the medical wards of the Cincinnati Hospitals, and the others were, chiefly, men in apparently good health, inmates of the work-house, old men's home, on the police force, etc. All examined were males, excepting 275 women in the Dayton Asylum, who were kindly examined by Dr. Clara M. Ellsbury. Of the 2106 persons the knee-phenomenon was missing in twenty-eight. Five of these had fully developed locomotor ataxia, twelve were still in the earlier stages of the same disease, while in the eleven remaining there were no other symptoms of disease of the cord.

We will speak of the cases of insanity separately, because, as Westphal has shown by the report of some cases with post-mortem examination,⁷ the absence of this phenomenon in such cases is in itself strong presumptive evidence of the existence of disease in the posterior column of the cord, and because of the special value of the absence of this phenomenon in diagnosing the form of insanity. I had been of the opinion from previous observations that, in obscure cases of mental disease, the absence of the knee-jerk should direct our attention toward general paralysis, and that it would have some weight in establishing the diagnosis of this disease. This opinion is supported, though not very strongly, by the results of these examinations.

Of the twenty-eight persons with abolished knee-jerk, twenty-three were cases of insanity, and of these ten were cases of general paralysis, two were still doubtful cases, perhaps general paralysis, and eleven had other forms of insanity, mostly dementia of

⁴ Ibid., XIV, 402.

⁵ Neurologisches Centralblatt, 1886, No. 3.

⁶ Ibid., 1885, No. 18.

⁷ Berlin kl. Woch., 1881, No. 1, and Archiv f. Psych. u. Nervenkrankheiten, xij, 77a.

many years' duration. So only about half of the entire number are cases of general paralysis, but when it is considered that at the time there were only a few cases of general paralysis in the asylums beyond the number here included, while there were over 1100 with other forms of insanity, the significance of these figures becomes much greater. Its diagnostic value becomes still greater when another clinical manifestation is considered with it, that is, the condition of the pupils.

In both locomotor ataxia and general paralysis there are often peculiar changes in the pupils, termed the Argyle Robertson phenomenon, or reflectory rigidity; they do not contract when light is thrown into the eyes, but contract during the act of accommodation. Moeli, Thomsen and Siemerling* found in 4000 insane persons 492 with rigidity of the pupils, 85 per cent. of whom had general paralysis.

Of my ten cases of general paralysis with absent knee-phenomenon, nine had pupil symptoms; of the two doubtful cases such symptoms were present in one, while they were only present in two of the other eleven patients.

If we can draw any conclusion from such a small number of observations we may safely say that, in an obscure case of mental disease, if the history would not oppose the diagnosis, the absence of the knee-phenomenon is some indication that the disease is general paralysis, and the additional presence of rigidity of the pupils makes such a diagnosis highly probable.

In the 932 non-insane persons there were five with abolished knee-phenomenon. Of these, two had other symptoms of locomotor ataxia; one was an old man of 94, with considerable degeneration of all the tissues, and only two were apparently healthy. One of these was a colored man of 39, who had had a venereal sore, and suffered occasionally with pains about his trunk of an aching character, but had no other symptoms and was apparently in perfect health. The second was a man of 25, who stated that he had never had venereal disease, and was apparently in perfect health. Both were inmates of the work-house. Thus, in 929 persons only two had no knee-phenomenon. It is possible that in these there is some incipient disease of the cord, but whether this be true or not the number is so insignificant that, especially when we compare the results here obtained with those of Jendressik, we may boldly state that the absence of the knee-phenomenon is almost a pathogenic sign of disease, that disease being usually sclerosis of the posterior columns of the cord, locomotor ataxia.

That the phenomenon is sometimes absent in other pathological conditions, scarcely detracts from its diagnostic value, for the other conditions can usually be distinguished. Anterior poliomyelitis can not be confounded with locomotor ataxia. Neuritis is often only a partial manifestation of locomotor ataxia. Diabetes mellitus and alcoholism scarcely need mention in this connection. Diphtheria occurs chiefly in children, where the question of locomotor ataxia scarcely arises; yet it might occasionally, in cases of

adults, be a source of confusion, as the knee-phenomenon is sometimes abolished without any diphtheritic paralysis, but it would reappear in time.

It does not appear to me that the phenomenon is as frequently abolished in diabetes mellitus as the results of some observers would lead us to infer. Rosenstein* missed it in six of nine cases, and Bouchard* in nineteen of sixty-six cases of diabetes mellitus. But I have recently had an opportunity to examine five cases, and found it present in every one of them. In one the phenomenon was very slight, but in this patient the presence of the peculiar lightning pains of locomotor ataxia, a considerable anæsthesia and greatly impaired gait make it very probable that there are structural changes in the cord.

The absence of the knee-phenomenon in chronic alcoholism is probably very rare. I examined 404 men in the work-house, many of whom are hard drinkers. I also examined quite a number of cases at the hospitals. In none of these was the phenomenon absent, although in two, at the Cincinnati Hospital, it was very difficult to elicit. It is said that in such cases the phenomenon is only temporarily abolished, and can be restored by the administration of strychnia, but this remedy has no such effect in locomotor ataxia. I have seen several cases of the latter disease, in consultation, in which strychnia had been administered, the knee-phenomenon, nevertheless, remaining absent.

We may then judge from the foregoing how significant is the absence of the knee-phenomenon, and how much it may aid us in diagnosing incipient locomotor ataxia. But in order that it should possess so much value, that it may not altogether mislead us, our examinations must be made carefully, and the phenomenon not pronounced to be absent when it can really be elicited. I have again and again had persons presented to me with the statement that in them the knee-jerk was absent, where I easily succeeded in eliciting it. Especially has this been true of physicians themselves, and in many instances it was with a sense of relief that they learned that their self-observations had been incorrect. Such errors are so common, and might be so misleading, that it is well to speak somewhat at length of the methods of examination.

The ordinary mode of examination, striking upon the *ligamentum patellæ*, while the subject is sitting with one knee crossed over the other, will suffice in most instances, for usually the phenomenon is easily elicited. But it is sometimes difficult to elicit, either because the subject can not altogether relax his muscles, or from mechanical difficulties, or from no assignable cause. Even in the same individual the phenomenon, while easy to get sometimes, may be very difficult to elicit at others. In such instances the individual should be seated on a table with the legs dangling, and the knee entirely bare, and then the patellæ tendon should be struck upon every part. The best instrument, in my experience, is the inner edge of the hand. In this manner the phenomenon can be elicited in the great majority of healthy persons. Perhaps the failures to be expected are prop-

* Berlin. kl. Wochens., 1886, 37.

* Ibid., 1885, 113.

erly represented by Berger's results, who failed to get the phenomenon in 11.6 per cent. of his cases.

But Jendrassik has quite recently suggested a method of examination which reduces this relatively large per centage to almost zero. This method enabled him to find the phenomenon in all of 1000 persons except one; it was the means of obtaining the phenomenon in the one child of the 2403 children examined by Pelizaeus, in whom it could not otherwise be obtained, and it enabled me to obtain the results reported in this paper. The method is as follows: The individual, seated as above, is requested to link the bent fingers of one hand into those of the other and pull energetically. During this effort the examiner strikes the patellæ tendon. The effort heightens the muscular tonus, or increases the tension of the muscle and tendon, and makes the knee-jerk more marked. In sixteen of the 1000 examined by Jendrassik he was unable to obtain the phenomenon by the ordinary method, in fifteen of whom he easily obtained it by his own method. In my own examinations I succeeded in quite a number of instances in getting the knee-jerk with Jendrassik's method when I could not do so otherwise. Indeed, so striking was the difference in some instances that it occurred to me that this method might enable us to get the phenomenon in locomotor ataxia. For that reason I again examined a number of cases of that disease in which I had previously pronounced it absent, but in all of them, notwithstanding Jendrassik's method, the phenomenon still remained absent.

Jendrassik states that in his 999 cases he obtained the knee-jerk easily by his method. This was not my own experience. In some instances it was very slight and obtained with difficulty. Whether such a result always has a pathological significance I can not say. In some of these instances the persons examined seemed to be in perfect health; in others there were other manifestations of disease. The latter is especially true of some cases in my case book, and not included in this report, in some of whom there is undoubted locomotor ataxia, in its early stages; in others there is some reason for suspecting the presence of the disease.

Is the knee-jerk always absent in locomotor ataxia? Westphal stated in his earliest publication that it is always absent in typical cases, at least when the disease involves the lumbar portion of the cord. As the disease generally begins in this part, the loss of the phenomenon is usually its first manifestation. Since Westphal's publication, various cases have been reported in which the phenomenon remained present. Hirt¹⁰ recently reported a case in which the phenomenon remained during life, and the post-mortem examination revealed the characteristic changes in the cord; but he was unable to state from the examination of the fresh specimen whether those parts were affected, whose disease Westphal believes to be accountable for the absence of this phenomenon. Westphal¹¹ has shown in a case of his own that a skin reflex action may sometimes simulate the patellar tendon reflex, and cause us to suppose the latter is

present when it is really absent; but he also has reported two cases in which the phenomenon was still present after the ataxia gait was fully developed, and only disappeared in a very late stage of the disease.¹² But such instances are rare, so rare as to very little invalidate the worth of the phenomenon. I have seen quite a number of cases of this disease, and in only one of them was the knee-jerk in its normal condition. This case (which I reported in the *Journal of Mental and Nervous Diseases*, 1884), was not one of typical locomotor ataxia. There was considerable muscular atrophy, and the whole appearance of the case was that of a diffused myelitis, rather than of a systematic disease of the posterior column. In several other cases now under observation the phenomenon can be obtained slightly on one side, but in none of these has the disease advanced to the stage of ataxia.

In conclusion, we may summarize our results by saying that if, in any person, with no other assignable cause, we find an entire absence of the knee-phenomenon, we should look for other symptoms of locomotor ataxia, and if any other symptoms are presented the diagnosis is assured. But before pronouncing it absent the patient should be carefully examined, especially by the aid of Jendrassik's method. In some instances it would even be well to examine several times before pronouncing a final verdict, partly because there is sometimes such difference in the degree of response at different times in the same individual, partly because an unrecognized attack of diphtheria, or the like, may have caused its temporary disappearance.

It was my intention to speak also of the significance of excessive tendon reflexes, but on account of the length the paper has already assumed, I must forego further consideration of the subject.

In addition to those already mentioned in this paper, I am indebted to Dr. Kiely, Physician to the Work-house, Drs. Armstrong, Isham, and Dun, who are at present examining the city police, and Dr. B. F. Clark, Surgeon to the C., H. & D. R. R. Co., for valuable assistance in collecting the material here utilized.

INTUBATION OF THE LARYNX FOR DIPHTHERITIC CROUP.¹

BY FLETCHER INGALS, A.M., M.D.,

PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE; PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE, CHICAGO.

Some time ago I reported two cases of intubation of the larynx in children less than 3 years of age, both of which proved very satisfactory at first, but both died within two days. Shortly after that report I introduced the laryngeal tube in a child about 5½ years of age. There was immediate relief from dyspnoea; the child expressed herself as thankful that it had been done; the friends and the attending physician (Dr. Creighton) were all much pleased, but the

¹⁰ Ibid., 1886, 153.

¹¹ Archiv. f. Psychiat. u. Nerven., XII, 798.

¹² Neurologisches Centralblatt, 1886, No. 6.

¹ Presented to the Chicago Medical Society, June 21, 1886.

child sank and died of diphtheritic bronchitis within thirty-six hours.

Recently I have had two more fortunate cases, which have led me to believe that ultimate success may be due largely to the subsequent treatment. *Case IV*, the first of these, J. R., was a little girl 4 years of age, to whom I was called by Dr. E. Garrott on May 26. The child had suffered from a "bad cold" for five or six days, and had been croupy for forty-eight hours. When Dr. Garrott first saw it there was labored respiration, with recession of the chest walls with each inspiration. He sent for me as soon as possible, and we at once decided that intubation or tracheotomy would be necessary. I introduced the laryngeal tube without delay, and shortly afterwards the patient coughed up quite a large piece of false membrane. We directed that the child should be fed on soft solids and that fluids should be withheld as far as possible. We prescribed calomel, which was given in doses of from $\frac{1}{2}$ grain to 1 grain every two or three hours for the next three days.

Whenever any fluid was given it was by the half teaspoonful, and we finally found that this could be swallowed slowly as the child lay on her side without exciting cough. She was allowed all the ice she wished to quench thirst. There was considerable fever for two or three days, the temperature running between 102° and 103° F., but on the fourth day this had nearly disappeared. During this time mucous râles had been abundant over the whole chest. At the end of the fourth day the child triumphantly displayed to her friends the tube which she had just extracted by her own efforts, without cough, remarking that she knew she could get it out. There was no difficulty in breathing subsequently, and at the end of the sixth day the patient appeared perfectly well. In this case expectorants were given beneficially during a part of the treatment, and moderate doses of calomel were given for the first three days. The voice became natural about twenty-four hours after the tube had been expelled.

Case V.—On June 3 I was called by Dr. Lilly to see a little girl, I. D., 4 years 8 months old, suffering from diphtheritic croup. The child had been sick forty hours, having been taken with difficult breathing during the middle of the day. When I first saw her there was great dyspnoea, with lividity of the face and recession of the chest walls; the symptoms indicating speedy death. As Dr. Lilly was obliged to leave the city I was asked to take charge of the case. With the assistance of Dr. E. Ingals I easily introduced the tube, which gave the patient immediate relief. I directed that not more than a half-teaspoonful of fluid be given at any time, and this very seldom. Soft solids were ordered and the child was allowed to suck ice when she wished it to quench thirst. My directions as to fluids were not thoroughly carried out in this case, and to this fact I attribute some of the subsequent trouble; for every time fluids were taken cough was excited, showing that some of it passed into the trachea. I at first prescribed hydrarg. chlor. mite, gr. i every second hour, and a 1-grain tablet of quinine and chocolate every fourth hour.

Twelve hours after the tube had been inserted I found the respiration easy, but the temperature was 104° F. in the axilla. In the evening of the same day, twenty-four hours after the tube had been inserted, I found the patient in a most critical condition. Sonorous and sibilant râles, and that ominous dry tubular respiration which we have often heard after tracheotomy, were to be found all over the chest. The patient was extremely restless, face becoming livid, pulse irregular, rapid and very feeble, respiration imperfect and sighing, urine scanty, and the temperature in the axilla $104\frac{1}{2}^{\circ}$ F. Indeed, she presented all the symptoms of the last stage of diphtheritic bronchitis. I have observed such symptoms frequently, but never before have I seen the patient live more than three or four hours after they had become as marked as in this case. In this emergency I ordered respiratory and cardiac stimulants, prescribing tinct. nucis vom. m i, ammon. carb. gr. i, syr. ipecac m xii, and potass. acetate gr. iv, in syr. glycyrr., every second hour, to be given alternately with the powders of the mild chloride.

The next morning the breathing was somewhat improved and the temperature 104° F. The pulmonary signs were a little better, but not at all satisfactory. I then discontinued all other medicines and ordered tinct. nucis vom. m i, ammon. carb. gr. i, potass. acetat. gr. iv, and syr. ipecac m xxiii, in syr. glycyrrhizæ, to be taken every hour. The relief obtained from this medicine was very pronounced. During the afternoon of the second day, forty hours after the tube had been inserted, it was coughed out. I saw the child about an hour later and found considerable difficulty in inspiration, with some recession of the chest walls. I could not reintroduce the same tube without using too much force, but I had no difficulty in inserting the next size smaller, which at once relieved the stridor.

In the evening the patient was much better and moist râles could be heard over the whole chest. The next morning the temperature was $101\frac{1}{2}^{\circ}$ in the axilla.

On the fourth day after the first intubation the second tube was coughed up, but there was no necessity for its reintroduction. The child talked in a whisper, less distinctly after the tube was expelled than before. From this time on the child improved, though the signs of diphtheritic bronchitis continued. The medicines were gradually withdrawn, though they had to be given again on two or three occasions when the cough became dry.

At the end of a week the bronchi of the left lung had been mostly cleared, and the child appeared to be nearly well. On the thirteenth day I noticed the first improvement in the voice. On the eighteenth day the voice was still weak, and bronchial râles had not entirely disappeared, but otherwise the child appeared perfectly well.

Though in this case there had been no appearance of diphtheritic membrane in the fauces, there was no doubt about the membranous character of the disease; besides, its true nature was partially proven by the fact that the child's little nurse came down with diphtheria during her illness.

These cases illustrate the necessity of great care

in the subsequent treatment after intubation for diphtheritic croup. We must not forget that we have to deal with a serious disease even though the larynx may be kept open. We must not forget the danger from the entrance of food or fluids into the trachea, and we must use every possible precaution to prevent it. If we analyze the reports we find that a very large percentage of the cases of intubation of the larynx have died of pneumonia, and this was undoubtedly due largely to the entrance of foreign substances. I believe that when we attend carefully to the administration or non-administration of food and drinks, and when we promptly meet the indications for expectorants and cardiac and respiratory stimulants, we will be able to save a much larger percentage of cases than shown by the present history of the operation.

The admirable paper just presented by Dr. Waxham shows that the results of this operation even now are quite as good as those of tracheotomy for young children. When we consider the ease with which this operation may be done, its freedom from danger, and its good results, we must consider any one grossly culpable who would allow a child to die from croup without giving it a trial. As parents and friends will readily consent to this operation though they would not to tracheotomy, it will be a means of saving hundreds of lives which would otherwise be sacrificed. When we look over the record and reflect that of the cases already saved by this method probably not 5 per cent would have been saved in other ways, and as we look into the future and see the immense possibilities of this operation, we must not forget our debt of gratitude to Dr. O'Dwyer for his invention, and to Dr. Waxham for his enthusiastic employment of it; but most of all to the profession at large, which tolerates no secret methods, but generously donates to mankind every improvement in the healing art.

64 State Street, Chicago.

THE TREATMENT OF ASIATIC CHOLERA.¹

BY S. S. TODD, M.D.,

PROFESSOR OF DISEASES OF WOMEN, KANSAS CITY MEDICAL COLLEGE.

Nearly two years ago, in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION (Vol. III, No. 6), I called attention to a proposed method of treating Asiatic cholera, in which the injection of large volumes of warm distilled water into the areolar tissue, at convenient points and at short intervals, and the use of hot water drinks acidulated with sulphuric acid, were the leading features.

In May of last year, at the annual meeting of the Missouri State Medical Association, when the treatment of this disease was under consideration, I again took occasion to express my confidence in the method, and my growing belief that I had suggested what may at least be deemed a reasonable plan of treatment of the disease in question.

At the time of my first publication I believed the

treatment proposed by me to be entirely new; but the publication eliciting comment from various learned sources, drew from Dr. George A. Staples, of Dubuque, Iowa, some information on the subject unknown to me before, and which led to the inference that while my plan of treatment was *mainly* new, it was not *wholly* so.

In the article by Dr. Staples referred to, and which appeared three weeks after my publication, the doctor in a spirit of the utmost kindness shows that in 1883, and again in 1884, Prof. Samuel, of Königsberg, Prussia, published a brochure on "Subcutaneous Infusion as a Method of Treating Cholera," in which he says that during an invasion in 1866 he "repeatedly injected substances into the calves and epigastrium." He does not name the substances used, nor does he give the result. In a subsequent publication in the *Berliner Klinische Wochenschrift*, in 1884, the same writer reiterates his views, which seem to favor subcutaneous medication, and relates a case in the hands of another practitioner, Beigel (*Lancet*, II, No. 13, p. 352), in which, there being "complete collapse," hypodermic injections of warm water to the extent in all, at first, of seven ounces, were made into the calves, thighs, and arms. Some improvement following the measure, Beigel made two further attempts, but the patient finally succumbed.

These publications, which, so far as is known, had never been translated into English, had escaped the observation of the writer up to the time when his publication in THE JOURNAL was made, and he must be excused, therefore, for not having made mention of them. So ill-defined, however, were the ends sought, and so inadequate were the means used in these cases, that the treatment adopted seems to have been almost without purpose and without hope, and certainly without that vigor of execution that is born of strong conviction.

Practically, at least, my claim of having suggested a new method of treating the disease is for the present unchallenged. The hypodermic use of many "substances" has long been practised. The "substance" in the case cited was warm water, given "in all" to the extent of seven ounces only. After this two further attempts were made on the same patient, but the quantity of water used is not stated. It is only said that the patient finally succumbed. *Sed hæc hactenus*. The writer would avoid the imputation of having set up false claims to originality in this respect, and therefore gives the facts as cited by Dr. Staples; but those who have read the paper in No. 6, Vol. III of THE JOURNAL, will readily see, perhaps, that the writer's claim to originality does not need a chronological basis.

In view of the fact that another visitation of cholera may be expected soon, and the great fatality that has hitherto attended the disease under all kinds of treatment, the writer will probably be pardoned if he again urges his views for trial when the opportunity shall come.

I would advise the following plan of treatment to be pursued, with *watchfulness and stern determination*: All cases in their incipency, and *mild* cases throughout the attack should be treated with opiates

¹ Read in the Section on Practical Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

and astringents, and *hot* water acidulated with sulphuric acid should be allowed, and urged upon the patient, to the utter exclusion of ice, ice-water, and all ice-cold drinks. The abdomen should be covered with a large mustard poultice and bandaged.

In a more advanced stage of the disease, and in all severe cases from the outset, no time should be wasted with opiates and astringents. They cannot now be of any advantage, and may do a great deal of harm. Collapse is imminent, and the hot drink should be given more assiduously than before, and repeated again and again, if the stomach shall seem to reject it, with the hope of maintaining the normal temperature of the stomach, at least, and assuaging the painful retching. Ice and ice-cold drinks, contraindicated in all stages, are most hurtful in this, and however grateful to the patient, and however eagerly craved, should be rigorously excluded, as tending to cause, or aggravate an already existing algid condition.

It is at this juncture that the physician with only the ordinary resources at command begins to feel his helplessness. "Is there no remedy that repeated trial has not condemned as worthless?" he says to himself, silently and hopelessly. The blood is losing its serum, the patient's voice is growing husky, his mind is growing indifferent, his extremities are growing cold, his skin is growing livid, his blood is growing thicker, capillary circulation is being suspended. The fluidity of the blood must be maintained, or restored, the brain and nerve paresis overcome, or death will speedily ensue.

Now, without having an opportunity of giving the plan a trial, the writer ventures to suggest that the most rational treatment in such a case would be to flood the circulatory system with pure water to which a little common table salt has been added—24 grains to 16 ounces of distilled water. To this may be added alcohol, or, what is better, probably, a fluid drachm of tinct. cantharides, for the writer has had ample proof of the virtue of cantharides as a vaso-motor stimulant, and as a remedy for the relief of painful muscular contractions in such cases, when given hypodermically. This quantity—a pint, for a single injection, in the adult, less or more according to the stage of the disease and degree of urgency, age of the patient, and amount of serum being lost.

These injections should be begun, if possible, *before sensibility has been much impaired*, and should be made at a point, or points, not distant from the head—points about the chest or neck are best—and the fluid should be injected no faster than it shall be absorbed. This operation may be repeated every hour, or less frequently, according to the demands of the case, for it must not be forgotten that this proceeding is intended to replace the fluid lost by the skin and bowels, and the amount of fluid thus thrown into the circulation is to be determined accordingly.

There is one question of great importance that presents itself—will the fluids thus injected into the subcutaneous areolar tissue be absorbed? This question, if we may judge from the tenor of the comments made on the writer's first publication, is the main obstacle in the way of many to a general acceptance of the proposed practice. Fortunately, it is a question

that may be settled speedily and safely when the opportunity offers. That it will be settled affirmatively, the writer does not doubt, from results of like treatment in like adynamic states in several cases of marked gravity.

At the suggestion of the writer Messrs. George Tiemann & Co., 67 Chatham St., New York, have made a syringe especially for this purpose. The instrument has a capacity of four ounces, with three needles of different sizes, and will find ready use in many ways, as for exploratory aspiration, for the emptying of small, deep-seated abscesses, and for the injection of alcohol in large quantities in any adynamic condition.

MEDICAL PROGRESS.

TREPHINING UNDER COCAINE.—At the meeting of the Practitioners' Society, of New York, on May 7, Dr C. L. DANA related the following case, the hospital notes having been taken by his house physician, Dr. J. M. Kingman: William H., single, aged 38, born in Ireland, a bricklayer, was admitted to the hospital, February 17, 1886. Examination, February 19: The patient said that his father had had fits. The patient himself had a fit about ten years ago; he fell backward and was unconscious for about twenty minutes. Otherwise he had been a well man until eight months ago. He was then hit on the back of the head by a bar, and remained unconscious for some hours. A day or so later he began to notice difficulty with his speech—a halting and stammering. He also began to notice loss of power in his legs and arms, which has remained about the same.

Dr. Dana decided to trephine the patient. The operation was performed by his late house physician, Dr. Symonds. The patient was a rather weak man, and as Dr. Dana had several times seen epileptic patients get an attack under the influence of ether, he thought it proper to try cocaine instead of ether as an anæsthetic in this case. The head was shaved, and about fifteen minims of a four per cent. solution of cocaine was injected into the skin in the region of the scar which had been left by the blow.

The injection was made deeply, so as to reach the periosteum. Subsequently other injections were made as needed. After the periosteum had been raised and the trephine applied to the bone, no more cocaine was used, as no pain was complained of. About one drachm of the four per cent. solution was employed during the whole operation, which lasted an hour and a half, including the final dressings. At first he employed an incarcerating coil of tubes, applied by the aid of an Esmarch bandage in the way described by Dr. J. W. Wright, but the bandage was so uncomfortable, and finally painful, to the patient, that it had to be removed, and the major part of the operation was performed without any incarcerating coil whatever. The operation, for several reasons, was somewhat prolonged, but the patient endured it without complaint, sitting in a chair with his head resting on his arm on a table in front of him. The incision

was made over the occipital bone on the left side, near the junction of the temporal bone, and three inches to the left of the occipital protuberance. A depressed fracture, linear, and over an inch long, was found. The anterior portion showed some loss of bone-substance, which was replaced by fibrous tissue.

A large button of bone was removed, which showed some depression of the internal table. Pieces of bone were also removed with the forceps.

The exposed dura mater did not appear to be sensitive.

After the operation the patient had one fit the next morning and two others a month later. Since then he had remained free from attacks, though taking the same dose of bromide as before (gr. xlv. daily). His mind was much clearer, his speech greatly improved, and he was able to walk alone, when before the attack he could not walk at all, except with the support of attendants.—*Medical Record*, June 26, 1886.

ALUMINIUM BRONZE IN MEDICINE AND DENTISTRY.—PROF. C. SAUER, of Berlin, says in regard to this substance: Aluminium bronze, which I have utilized for the under layer of teeth-plates, is entirely free from injurious oxidation. For this purpose and in teeth-straightening machines, it admits of easier manipulation than gold alloys or silver. I believe, therefore, that it might be of use in the manufacture of surgical instruments. Canulas, sounds, catheters, etc., might be made, and everything that is manufactured from silver. It is an alloy of 900 copper and 100 aluminium. It admits of almost as ready stamping and pressing as pure silver (which next to pure gold, is the softest metal), and it has besides the elasticity of steel. In form of wire, aluminium bronze possesses a power of resisting tension approaching that of steel wire. These characteristics render the aluminium bronze capable of substitution in many cases for silver, and for silver and gold alloys. I have found the melting-point of the aluminium bronze to be higher than that of pure gold, 1000° C. It may, accordingly, be made red-hot without danger of melting, and manipulated with hard solder. I solder it with from 14- to 16-carat red gold, and such solder is more capable of resisting chemical influences than the silver solder, which contains zinc. 10 grms. of aluminium bronze, in the form of a lead plate, are worth 25 pfennige (6 cents), while 10 grms. of 12-carat silver, in the form of a lead plate, are worth 1 mark 50 pfennige (37 cents); 10 grms. 14-carat gold cost 19 marks (\$4.75). Aluminium bronze is one-half lighter than 12-carat silver, and almost half the weight of 14 carat gold.

For testing how aluminium bronze is preserved in the mouth, I have employed the galvanic current. Pure aluminium, with other metals, in the presence of a acid or an alkali, yields a galvanic current. Years ago, in experiments with the mouth, I found that in a combination of aluminium with zinc the latter oxidizes. In manufacturing a combination of aluminium with gold alloy or platinum, under such circumstances, the aluminium, on the contrary, decomposes. In two cases in which it was possible for me to weigh pieces of aluminium bronze placed in

the mouth, under the influence of a possible galvanic current, and the pieces not being cleaned, and therefore not mechanically worn, after the lapse of four weeks I noticed no loss of weight. For instance, with a piece weighing 16 grms. I have been able to discover only a loss of 0.008, and, besides, after first weighing the piece, a screw was afterwards inserted, so a very slight mechanical loss of weight, therefore, took place. The aluminium bronze oxidizes only superficially in the mouth. There forms upon it a kind of patina, such as is formed in the weighing of plates of 14-, 16-, 18-, and even 20-carat gold. It admits of manufacture into spiral springs, plates, screws, canulas, etc., for surgical purposes. Even knives have been manufactured therefrom. A solution of corrosive sublimate of 1 to 1000 affects it superficially. For its disinfection carbolic acid is to be preferred, as it does not attack the aluminium bronze. Gold aluminium bronze acts similarly, but oxidizes to a greater extent, is softer, and not so elastic, and therefore is to be used as green gold or 20-carat gold is used.—*Therapeutic Gazette*, June 15, 1886.

VISCERAL LESION OR DISORDER, AND MENTAL DISEASE.—DR. JAMES ADAMS says: Disease, or disordered function of internal organs, it is well known, go hand in hand with well pronounced mental disorder. Although it cannot be stated with perfect certainty that these stand to each other in the relation of cause and effect, this much may, at least, be affirmed, that bodily disease or disorder not unfrequently determines the character of delusion, or the form which mental disease assumes.

Thus, the childless wife, past her climacteric, finds, as the effect of an epitheliomatous uterus, the pains which she fondly brings herself to believe are the long-looked, and wished-for, pains of labor; whilst the maniac of persecution, traces in the agonies of pain which he actually undergoes from organic visceral disease, only the cruel influences and machinations of his enemy, or the evil one, upon him.

An interesting case of delusion, stated to be the result of intestinal accumulation, was reported in the *British Medical Journal* of April 10th; a similar case has since come under my own care, a brief report of which may also prove of interest.

My patient, a married lady, is about 50 years of age. She has always been healthy, has had a family, and there is no trace of hereditary tendency to mental disease. The duration of mental unsoundness, when she came under my care, was said to be about three weeks. Its cause was stated to be anxiety in family matters. The mental symptoms had been great melancholy and depression; determined opposition when asked to do any ordinary or rational thing; obstinate refusal of food; constant restlessness; tossing her hair about and tearing it; walking about in her night-clothes; violently refusing to be dressed. She was so violent that she could not be kept in any one position for a moment. She was absolutely incoherent in conversation; had not slept for many nights; and could not be controlled.

On examination, she was found to be violent and

resistive; her hair was in great disorder; she was constantly restless, moved continuously, swaying backwards and forwards from one foot on to the other. Her breath was offensive, and had the odor peculiar to abstinence from food. She was profoundly taciturn, incomprehensible, lost, and bewildered; and absolutely refused all food, nourishment, or even water. It was found necessary, in order to support her strength, at once to administer liquid nourishment by means of the stomach-pump; and this was, of necessity, afterwards repeated three times daily. At the end of a week, all medicines and enemata given having failed to work satisfactorily upon the bowels, and it having been ascertained that the same condition of things had been in existence three or four weeks previously, examination *per rectum* was made, when a dense and hardened mass of scybala was found; it was broken up, and partially removed by means of spoon-handles; and this, followed by a renewed enema of several pints, thoroughly evacuated the lower bowel.

Up to this time, the mental symptoms had continued as they have already been described, notwithstanding also a very large amount of liquid nourishment and stimulants administered mechanically; the tongue had remained dry, coated, parched, and parchment-like; the lips and teeth were similarly coated, the former becoming dry and excoriated. But, very soon after the free evacuation of the bowels, all the worst symptoms began gradually to disappear. Consciousness and comprehension returned, and attempts were made to partake of food and nourishment naturally. These favorable symptoms have steadily gone on since; and now, the third week of treatment of what promised to be a formidable and prolonged attack of melancholia, with stupor, finds the patient calm, coherent, sensible, industrious—with, in short, convalescence perfectly established, and discharge from care imminent.—*British Medical Journal*, May 29, 1886.

COMMENCEMENT OF DROPSY AS A POINT IN DIAGNOSIS.—Apropos of the subject of dropsy, there has seemed to me to be one very good mechanical indication for distinguishing whether dropsical effusion springs from disease of the heart, or from disease of the liver, or the first local seat of the effusion. If dropsical effusion begins in the lower extremities, and proceeds to the abdomen, the evidence is fairly sound that the obstruction is direct from the heart, and that the liver is free, the stagnation and transudation being due to a failure of the return column of blood from the extreme parts. If, on the other hand, the accumulation of fluid begins in the abdomen, and extends to the lower limbs, the evidence is equally good that the arrest of the circulation is in the hepatic system. This distinction may be of moment sometimes in deciding on the question of tapping. In a case where the dropsy occurred first in the extremities, and afterward in the abdomen, it would be good practice to delay the tapping until the effect of removing fluid by puncture of the lower limbs had been carried out. But in a case where the effusion is, primarily, into the peritoneum, and afterward into the extrem-

ities, tapping the abdomen would have a prior place to puncture. The rule would run, in cases where there are ascites and anasarca: Tap for primary ascites, puncture for primary anasarca. I refer, of course, in this note to chronic ascites and chronic anasarca uncomplicated; not to special dropsies of local origin, like ovarian cysts, and not to dropsy from renal disease.—*Asclepiad*, April 25, 1886.

FATAL RESULTS FROM "SPLITTING THE CERVIX."—Dividing the cervix at the external, or at the internal os, or in the intervening portion, though not long since a comparatively frequent operation for dysmenorrhoea or sterility, is now very rarely done. Most operators now turn to dilators for the treatment of cases where incision was formerly done; one wing of the army of gynecologists still fights under the same banner of mechanical uterine pathology, only in place of hysterotomes, its enthusiastic soldiers use dilators. Possibly it is only a question of time when many of the dilators will be placed in the grave beside the hysterotomes, if the teaching of men like Duncan, Schultze, and Williams prevails, and the mechanical theory of uterine disease is cast aside.

However this may be, we have been somewhat astonished to know of the mortality which Sims had from this operation. Pajot states, in a recent lecture, that he knew of at least four deaths of women upon whom Sims had performed his operation of division of the cervix, and he believes that other similar accidents happened to him. In the light of these facts, the profession is to be congratulated upon the fact that the operation has fallen into disuse.—*Medical News*, June 12, 1886.

TREATMENT OF ACUTE RHEUMATISM.—The last number of *Russkaya Meditsina* contains a communication from DR. L. GRINEVITSKI, of Rostoff-on-the-Don, who writes that for more than twenty years he has treated acute articular rheumatism with nitrate of potash, 2 drachms being given daily in raspberry syrup, and a dose administered every two hours. Together with this internal medication he prescribes an ointment for use morning and evening of the following composition: Olei hyosc., 1 oz.; ung. hydrarg. cinerei, 2 dr.; ext. acon., 1 dr. He has tried all ordinary remedies, and finds that on the whole this plan of treatment is more satisfactory than any other, being especially valuable in those cases where salicylates fail to give relief. Generally the disease is brought to an end in from one to two weeks, according to its severity and the time the treatment was commenced. When commenced at the onset of the attack, and before more than one joint was affected, the others were usually spared altogether.—*Lancet*, May 22, 1886.

TOTAL EXTIRPATION OF THE TONGUE.—DR. R. F. WEIR reports a case of true epithelioma treated by Kocher's method. The whole tongue being involved, it was drawn out and removed at the level of the hyoid bone, after the side of the mouth had been opened under the jaw. Patient was cured twenty-eight days after operation.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

SATURDAY, JULY 10, 1886.

LAPAROTOMY IN STRANGULATED HERNIA.

Should the abdominal cavity be opened near the site of a strangulated hernia? Or to put the question a little differently, should we perform laparotomy instead of or with herniotomy for a strangulated hernia? Such are the questions which arise on reading the introduction to a paper on "Laparotomy in the Treatment of Strangulated Hernia," in the *Annals of Surgery*, for June, 1886, by MR. C. B. KEETLEY, of London, which may be considered the sequel to some papers, letters and cases in the British journals by MM. Pye-Smith, Fenwick and Neale. Mr. Chavasse states that Mr. Crompton, of Birmingham, opened the abdomen in the linea alba, in 1860, just above the hernial aperture of an umbilical hernia which had been acutely strangulated for seven hours. "His intention was evidently to approach the seat of strangulation from its internal or abdominal aspect. But, finding the gut gangrenous, he desisted and laid the sac open." Thirteen years ago Mr. Annandale, of Edinburgh, wrote a paper on this subject based on a case, in which he said: "The cases which appear to me to be most suitable for this operation are: 1. Umbilical herniæ in the adult, especially if the coverings of the hernia are thin or ulcerated, or the hernia large. 2. Large inguinal or scrotal herniæ which have been recently reducible. 3. Herniæ in other regions in which, owing to special conditions, the usual operation cannot satisfactorily be performed." This operation is, however, only suggested when in those forms of hernia the condition of strangulation or obstruction gives rise to symptoms which absolutely necessitate operative interference, and when signs of gangrene or a history of old standing irreducibility are absent.

The principle of this operation, says Annandale, consists in making a small incision through the abdominal wall and opening the abdominal cavity near the hernia, instead of cutting into the hernial sac itself, or exposing it. One or more fingers are then to be inserted into the abdominal cavity and the protruding structures contained in the hernial sac drawn back from within. He performed this operation in 1878, in a case in which a strangulated right inguinal hernia had been reduced *en masse*. A three inch incision was made in the linea alba, midway between the pubes and the umbilicus. "A portion of the small intestines dilated with gas immediately protruded, and on passing my finger along in a direction towards the right iliac fossa, I felt that the gut was here caught and fixed in some way. This fixed portion was easily drawn toward the wound, and it was then seen to be a small knuckle of gut strangulated by the neck of a hernial sac. This sac was entire, and its neck lay in the general peritoneal cavity, and had the appearance of being somewhat everted toward this cavity. Above the obstructed gut the intestine was dilated; below it, it was contracted and flaccid. Slight and careful traction on the intestine from within, and at the same time gentle pressure with one finger on the neck of the sac in the opposite direction, at once relieved the strangulated portion, and drew it out from the sac." This patient fell a victim to the carelessness of his friends, who allowed him to rise during the night and strain at stool. He died ten hours after the operation.

On reading Mr. Keetley's paper it is evident that the idea with which he performed the operation—which he did in 1883, before he knew of the existence of Mr. Annandale's second paper—was quite different from Mr. Annandale's and other operators, Mr. Keetley's idea being to perform laparotomy as an *aid* not to make laparotomy a *substitute* for herniotomy. Mr. Keetley does open the hernial sac, and assumes it to be opened in speaking of the operation. And Mr. Harry Fenwick published a paper, with a case (*Lancet*, Sept. 26, 1886) under the title "Laparotomy as an Aid to Herniotomy," and speaks very highly of the advisability of the operation for those cases in which the size and condition of the loop of bowel prohibits pressure or forbids prolonged exposure. Mr. Annandale's indications for the operation have already been given: Mr. Keetley summarizes his views as to the indications as follows: 1. When in hernia of any class, a constriction having been divided, very exceptional difficulty is met with in reducing the intestine. This indication more especially has force when hæmorrhage from the notch is persistent or severe. Putting aside this important consid-

eration of the prevention of hæmorrhage into the abdominal cavity, this indication must be one of extreme rarity. 2. When the hernia has been quite recently strangulated and belongs to one of certain classes, namely: (a) congenital hernia in the male; (b) umbilical hernia? In the first class of cases it is to be done as an aid to, and in the second as a substitute for herniotomy. "Under *no circumstances* would I sanction division of the constriction from the abdominal aspect, nor can I imagine how any dilating forceps could be used to stretch the ring without injuring the contents."

Mr. Keetley purposely excludes femoral hernia from the second class, because, having regard to the very dangerous character of that affection, he thinks the surgeon will do the best for his patient by cutting down upon and incising the sac. He has also excluded, but more reluctantly and with some doubts, non-congenital inguinal in the male, and both congenital and non-congenital in the female, "because the completion of herniotomy by excision of the sac, with ligature of its neck, forms so satisfactory an operation in these cases." The reasons for which congenital hernia in the male are included are obvious; all operations of excision and ligaturing in this affection are very dangerous, and usually superfluous as regards a radical cure. "Dangerous as they are, they are not superfluous when a direct herniotomy with incision of constriction, etc., is done, because then they are called for in order to isolate the wound from the abdominal cavity. There is therefore here a strong argument in favor of letting alone the sac of a congenital hernia in the male, and of doing median laparotomy when such a case is seen to be in a state of recent strangulation. The very fact of strangulation in such cases suggests a small hernial aperture and the prospect of success with mild means of obtaining radical cure ultimately." It will be noticed that Mr. Keetley has placed a "?" after umbilical hernia in his classification. This was done with the feeling that the indication for laparotomy in such cases will be very doubtful; and certainly a positive contra-indication may exist. In case of a large sac, evidently containing a large mass of omentum, and with probably a history of irreducibility for months or years, what is to be done? "Should the surgeon be content to perform a small median laparotomy and hook back into the abdominal cavity sufficient of the hernial contents to relieve the strangulation (perhaps a single small knuckle of bowel), leaving the omentum? Or should he set to work in more heroic fashion, reducing the bowel completely, cutting away omentum, sac and superfluous skin, and sewing up the hernial

aperture? Keetley did the latter and the patient died; Chavasse did the former, and the patient lived. "But many a patient has been operated on in the latter way and lived, and all the other cases in which had been followed a practice resembling (but it is true not identical with) Chavasse's plan, have perished."

With regard to the technique of the operation Mr. Keetley thinks it of prime importance that the surgeon keep strictly in the median line of the body. The substitution of scissors for the knife after the skin has been divided will avoid waste of time in checking oozing and in securing and tying vessels. The scissors should not be sharp. Near the pubes it may be necessary to divide the pyramidalis from its attachment to the fascia in the middle line. It is not necessary to cut the recti in order to separate them, and it is neither necessary nor desirable to go too near to the pubes—unnecessary because the fleshy parts of the abdominal wall being movable will permit the median aperture to be pressed towards the hernial ring; and undesirable, because the farther we keep from the root of the penis the better for antisepsis. There is practically no objection to enlarging the abdominal wound, if necessary to insert two fingers instead of one. The wound should be sutured in layers: first the peritoneum, then the muscles, next the aponeurosis, both beneath and superficial to the recti if possible, and lastly the skin. Neglect of this precaution may lead to a ventral hernia. The catgut should be of the very best, and thoroughly aseptic. Of course if peritonitis were discovered at the operation the surgeon would take the opportunity to wash out the cavity and put in a drainage tube.

MORE SENSATIONALISM.

It appears that recently DR. B. A. WATSON, of Jersey City, N. J., a well-known and eminent surgeon, has been prosecuting a series of experiments on dogs for the purpose of ascertaining more accurately the effects of concussion on the spinal cord, both immediate and remote. He hoped thereby to lessen the obscurity which has hitherto existed on the subject and given rise to the expression of much diversity of opinion by medical witnesses in cases involving alleged spinal concussion from falls, blows, and railroad accidents. To imitate as accurately as possible the concussions of ordinary accidents, the dogs, under the influence of an anæsthetic, were dropped through sufficient space upon solid bodies, to be likely to produce a decided concussion. The subsequent symptoms were carefully noted for different lengths of time in different dogs the animals then killed with

chloroform, and the brains and spinal cords subjected to minute examination for ascertaining what pathological changes had been produced.

Dr. Watson conducted his experiments on his own premises and at his own expense, and so quietly that he seems not to have given annoyance to any of his immediate neighbors. But some rumors concerning the matter having reached the ears of the editors of the *Evening Journal* of Jersey City, a reporter was detailed to work the matter up in the usual sensational style. He appears to have visited the doctor's barn, and while talking with his coachman he heard some "whinings and scratchings of dogs," apparently on the floor above. And on this single remarkable item of information he founded half a column in the *Evening Journal* of June 3, with the following startling heading: "Story of Awful Cruelty—Torment Unspeakable Inflicted—A Physician in search of Knowledge puts Dogs to the Torture—A Machine for Inflicting Agony too great for Description." Of course this speedily brought upon the scene the President of the Society for Prevention of Cruelty to Animals, Mr. McAneny, and as the result Dr. Watson finds himself subjected to the expense of a legal prosecution, his motives impugned, and his character for unparalleled cruelty paraded before the public in the columns of the newspaper in the most reckless manner. It is claimed that Dr. Watson destroyed forty-one dogs in prosecuting his experiments, for which he ought to have received a vote of thanks from the whole population of Jersey City, on account of his having lessened, by that much, their chances of suffering from hydrophobia in the future. And if Mr. McAneny and the managers of the *Evening Journal* of Jersey City, had half as much regard for the character and suffering of individuals of the human species as they claim to have for dogs, they would never indulge in public insinuations or open charges of wanton cruelty and mercenary motives against an intelligent and honorable citizen until all the facts had been established by impartial investigation. It is well known to every intelligent physician and surgeon that the subject which Dr. Watson was investigating is involved in obscurity, and that every additional item of knowledge gained concerning it is of real value to the human race. Hence the public insinuation against Dr. Watson that he was practising unheard of cruelty on the dogs for the most mercenary motives in subserviency to a railroad corporation, is a ten-fold greater and more unjustifiable cruelty to him, to his family, and the profession to which he belongs, than would be the breaking of the backs of all the dogs in New Jersey.

THE SIGNIFICANCE OF THE TYPHOID BACILLUS.

FRAENKEL and SIMMONS report, in *Fortschritte der Medicin*, No. 4, 1886, their results in repeating Gaffky's experiments as to the inoculability of the bacillus of typhoid fever. Gaffky has obtained only negative results in inoculating this bacillus in animals of different species, but Fränkel and Simmons have been more fortunate in their results. By inoculating pure cultures of this microbe in the peritoneal cavity of rabbits and mice, they have had a great number of these animals fall ill only a few hours after the inoculations—the results in the case of mice being almost constant—with apathy, anorexia, and diarrhoea; but without an internal rise of temperature. All the animals in which the inoculations succeeded died before the end of the fourth day, and on post-mortem examination the following lesions were found: tumefaction of the mesenteric glands and spleen, the spleen having the external appearance of one recently removed from a case of typhoid fever in the human being. There was also tumefaction of the follicular glands of the intestines, and often considerable tumefaction, and sometimes ulceration of Peyer's patches. The ganglia of the axilla and of the groin were also red and swollen in the majority of the cases. In a small number of cases there were hæmorrhages into the serous cavities. There was no trace whatever of inflammatory reaction at the seat of inoculation.

The microbes with which the inoculations were made were cultivated in gelatin and on potatoes at an ordinary temperature; and it must be admitted that the results of the experiments are evidence as to the pathogenic properties of the typhoid bacillus. The inoculations caused some disease in the rabbits and mice, but was it typhoid fever? Of course this is a question which must remain undecided for the present. One point especially to be noted is that the experimenters could not induce the pathological lesions mentioned in rabbits and mice by injecting the cultures into the intestines; though A. Fränkel has recently communicated a disease to guinea-pigs by injecting cultures of typhoid bacilli into the duodenum, the symptoms of which were tumefaction of the spleen, mesenteric glands and of Peyer's patches, and in one case there was ulceration of Peyer's patches. It is a noteworthy fact that Fränkel and Simmons found the typhoid bacilli in the blood and tissues of the animals which died from their experiments. They are convinced that these bacilli continue to develop in the organs after death, even when portions of organs containing them have lain in alcohol for more than two days.

CHOLERA IN ITALY.—A despatch dated Rome, July 3, states that during the preceding twenty-four hours 155 new cases of cholera and forty-six deaths had occurred in the villages around Brindisi. This indicates a decided increase in the prevalence of the disease.

THE AMERICAN RHINOLOGICAL ASSOCIATION will hold its fourth annual meeting at St. Louis, Mo., on the 6th of October next.

SOCIETY PROCEEDINGS.

THE ASSOCIATION OF AMERICAN PHYSICIANS.

First Meeting, held in the Army Medical Museum, Washington, June 17 and 18, 1886.

(Concluded from page 24.)

DR. JAMES T. WHITTAKER, of Cincinnati, read a paper on

SPASM OF THE GLOTTIS IN RICKETS.

The author emphasized the fact that this accident belongs almost exclusively to rickets and dwelt upon the value of recognition of this fact, because rickets is generally speaking a curable disease, and the spasm of the glottis disappears with the successful treatment of its cause, while treatment addressed to the larynx directly remains without effect. He quoted from a number of authorities to show that this relation between the two affections is not so universally recognized in this country and England as in Germany and France. The two latest text books in Germany, Strimpell and Sichorst, declare, one that two-thirds, and the other that nine-tenths of all cases of spasm of the glottis depend upon rickets.

Spasm of the glottis is often the first sign to unmask rickets, for the other evidences of the disease are often attributed to other causes. Thus general malaise is attributed to dentition intestinal catarrh to errors in diet, fever and sweating to malaria, bone deformities to premature efforts upon the feet, etc. Spasm of the larynx indicates the stage rather than the degree of rickets, in that it occurs mostly in cases of rapid advance of the disease and does not appear in cases of slow progress. In the spring and fall, when rickets advances in leaps, spasm of the glottis has occurred in epidemic form.

Dr. Whittaker discussed next the various theories of rickets which continue to elude investigation to a degree characterized as exasperating. But facts accumulate which go to give it place among the chronic infections. The exemption of hot climates and mountains, Iceland, the Faroe Islands, the complete immunity of Davos, notwithstanding the improper feeding and improper hygiene of sucklings at these places show that faults in diet can not be the cause of it, and the symptomatology of it fits better among the chronic infections produced by specific causes.

Spasm of the glottis in the absence of any con-

stant lesion falls among the neuroses. The question as to the reflex of direct character of the irritation producing it, was decided after a review of the evidence in favor of the latter, and since Rosenbach has demonstrated the micro-organisms of tetanus, which often begins with, and may go no further than trismus, the maintenance of a mycotic theory, for the laryngospasm of rickets, may be adopted as the best provisional explanation. The mode of onset and character of the accident were next detailed and the symptomatology illustrated with a typical case.

The inefficacy of anæsthetics and all direct means of treatment, as by intubation, tracheotomy, etc., were mentioned next, and douches, flagellations, electricity, cold air, direct appeals to the skin on the first appearance of attack, were described as the best means of combating and more especially of preventing the attack. Cod-liver oil, and more especially phosphorous, which may be looked upon almost in the light of a specific, were considered the best means of speedily relieving the rickets, and thus removing the cause of the laryngeal spasm. It has the most favorable prognosis of all kinds of laryngospasm, as Monte lost but eight of 329 cases.

DR. A. JACOBI, stated that this was a subject in which he was much interested. As has been said, this is almost always due to rickets. Its causation may be the pressure of the enlarged glands about the neck irritating the nerve. When the rickets disappears, the spasm of the glottis disappears. The disease may be primary or secondary. In forty-nine out of fifty cases of spasm of the larynx the cause is rickets, and in forty-eight of these it is rickets of the cranium and of the meninges of the brain. When the cranium is opened we find congestion. Cranio-tabes need not be developed to any marked extent. Where we have a succulent cranium, we have succulent meninges and a succulent brain. There is meningeal hyperæmia and meningeal effusion in such cases. In regard to prognosis, if you have six weeks during which to carry out proper treatment, you may be sure that the child will lose its laryngismus stridulus, but during that time the child may die in an attack.

DR. WILLIAM PEPPER described a case of spasm of the glottis in whooping cough, in which the attacks were so severe that on several occasions, the child apparently died. Nitrite of amyl was successfully used for the relief of these attacks. It was found that a combination of one part of nitrite of amyl with nine of sulphuric ether gave the best results.

DR. JACOBI had recently used nitro-glycerine for a similar purpose. He had used it in inflammatory hydrocephalus in young infants, and I believe with fair results.

DR. EDWARD T. BRUEN, of Philadelphia, read some

NOTES ON SOME CASES OF DIAPHRAGMATIC PLEURISY.

Dr. Bruen said that the object of his paper was to briefly state the diagnostic features of a diaphragmatic pleurisy. He did not attempt a review of the interesting historical literature of the disease. He admitted that the diagnosis of this affection was often established at the post-mortem table, since the pro-

cess is often latent and frequently possessed few distinctive physical signs. Primary pleurisy of this part of the pleura he considered rare. It is oftener a complication attendant upon acute inflammatory processes in the adjacent pulmonary lobes, the costoparietal pleura, or in the liver or peritoneum. Under the foregoing conditions, invasion of the diaphragmatic pleura may be characterized by special symptoms, which may entitle one to designate this class of cases as acute inflammation of the diaphragmatic pleura. Inflammation of this portion of pleura may be a sub-acute or chronic progress developed in consequence of contagious sub-acute, or chronic inflammation or malignant growths. In such cases the process in the diaphragmatic pleura may become specialized by symptoms which should lead the clinician to differentiate the diaphragmatic pleurisy from the associated pathological changes.

In the acute form of this disease many of the more prominent and differential symptoms may be masked by the greater importance of the primary disease. As an example, the history of a case of croupous pneumonia of the right lung was related, which on the fifteenth day became complicated with diaphragmatic pleurisy. The case occurred in the month of March, and the diagnosis was confirmed by autopsy on the twenty-fifth day after the illness commenced. The patient was delirious, yet many of the characteristic symptoms were grouped in this case, including hiccough, only controllable by rest and morphia, a somewhat diagnostic feature.

The symptoms of diaphragmatic pleurisy may also be masked if the liver be enlarged or the intestines distended with gas, for these conditions may sensibly modify the freedom of the diaphragmatic movements, and the immobility of the diaphragm, one of the prominent symptoms of diaphragmatic pleurisy may not be differentiated and assigned to its true cause; but sometimes the characteristic pain over the situations elsewhere designated and the added disablement of the respiratory function may be noticeable. Diaphragmatic pleurisy in the writer's experience was chiefly right sided.

The terminations of the acute cases are dependent upon the associated pathological processes, and the gravity of the case is not necessarily increased if the symptom of hiccough is subordinate, the latter being an exceptional uncontrollable and exhausting symptom. In primary cases, a favorable issue may occur.

A case of diaphragmatic pleurisy in a negro was related, and attention specially directed to the interference with the lymphatic pulmonary circulation, and the disseminated areas of congestion which were secondary, also to some oedematous bosses, which formed over the right hypochondriac region. These were attributed to interference with the lymphatic circulation in the diaphragmatic pleura, and the intercostal tissues on account of the suspended functional play of the diaphragm and intercostal muscles. Recovery ensued in this case at the expiration of five weeks.

To show that the diaphragmatic pleurisy may progress to a marked degree without the manifestation of diagnostic symptoms, the case of a negro man was

related, in whom post-mortem examination showed lesions of general miliary tuberculosis with marked thickening of the diaphragmatic pleura. It was shown in this case that the peritoneum was infected through the connecting channel of lymphatics between the pleura and peritoneum. During life some friction râles were heard along the upper border of the fifth rib and near the margin of the seventh in the axillary line, although a large amount of fluid was contained in the chest. The autopsy showed that the lung rendered rigid and thick by the tubercular infiltration, projected as a rigid mass into the pleural space, displacing the fluid and then the separation of flakes of exudation, doubtless produced the râles. It was stated that in the sub-acute or chronic cases, the special symptoms, diaphragmatic pleurisy were more conspicuous than in many of the acute forms of the disease. Illustrative cases were cited, one occurring in the Philadelphia Hospital, secondary to the induration of the right apex and general emphysema, in which the disease was correctly diagnosed and the post-mortem examination made. The possible variation in the symptoms was considered and then a case of congenital deficiency of the diaphragm was described. The patient was 32 years old at death and had lived twenty-four years without a symptom to call attention to the anomaly. In the latter eight years of his life, asthmatic symptoms and shortness of breath were found to be due to thickening of the pleura and to phthisis. A case of diaphragmatic pleurisy reported by Dr. Tyson, without special symptoms was discussed; also one by Dr. Daland. A case published by Dr. Pepper was cited, in which certain symptoms seemed consonant with those of diaphragmatic pleurisy. The whole thickness of the diaphragm was from one-half inch to two inches. The thickening was due to a morbid growth.

The diagnosis of a disease in which there is often so little that is distinctive, must necessarily be a difficult problem. It was shown by the relation of several post-mortem examinations that the process can exist in advanced form on one side of the diaphragm, at least, without special symptoms. If the diaphragmatic pleurisy should complicate any form of pulmonary hepatic pathological process, or circumscribed peritonitis of the superior part of the abdominal cavity, one may note that the subjective sense of respiratory distress and the objective symptoms are disproportionate to those conditions, and therefore the possibility of the existence of diaphragmatic pleurisy should be considered.

The more important diagnostic symptom, which, if present, should direct attention to the possibility of diaphragmatic pleurisy, are ranged in the order of their frequency and importance as follows: subjective sensation of pain over the zone which borders the diaphragmatic plane, pain at the point described by Dr. Mussey, viz., one or two fingers breadth from the middle line on a level with the tenth rib, or at the intersection of a line drawn from the osseous part of the tenth rib and one drawn along the sternum. Dr. Mussey explains the greater pain at this point by the greater play of the ribs and consequent friction against the inflamed nerve. Whether the nerve is actually

inflamed or simply irritated, must be decided by further investigation. The pains may be constant, yet also paroxysmal or provoked by pressure, or by increased respiratory motion by irritation of the diaphragm, swallowing or vomiting, or by the pressure of the distended abdominal viscera. Radiating pains around the chest and upper abdominal zone may occur. Fixation of the diaphragm is an equally important symptom, and secondarily the enforced thoracic character of the respiration is a very striking phenomena. There will usually be feeble or absent respiratory murmur near the diaphragmatic zone. Dry or moist friction râles may be audible along the convex surface of the diaphragmatic pleura. The percussion resonance may be dull when there is much exudation, but more commonly it is tympanitic since the partial paresis of the diaphragmatic muscle permits the pressure of the abdominal viscera to raise it somewhat above its usual area. In certain cases the posture of the patient may be bent forwards with hyochondriac retraction and epigastric hollowness, but the dorsal decubitus is very often maintained. The respiration is quickened in a few cases so that there may be dyspnoea or orthopnoea, but these symptoms may be almost entirely absent in sub-acute or chronic cases on account of the compensatory costal respiration. Cough is a variable symptom and the same may be said of hiccup, both are often absent. Finally, in the writer's experience, diaphragmatic pleurisy has been chiefly a thickening with adhesions, rather than accompanied with much fluid effusion. Hence, the importance of noticing the foregoing symptoms, since the presence of much fluid effusion would be more obvious by means of percussion, auscultation and other physical signs.

The necessity of differential diagnosis between costo parietal pleurisy processes in the lower pulmonary lobes or pericardium were alluded to, also, perihepatitis, circumscribed peritonitis in the upper part of the abdominal cavity. The exclusion of gastric ulcer and gall stones were discussed briefly and chronic pericarditis.

The prognosis was stated to be intertwined with the intercurrent pathological processes, and the power of adaptation possessed by the pulmonary system is so great that the duration, even of diaphragmatic pleurisy may be indefinite.

DR. T. MITCHELL PRUDDEN, of New York read a
DEMONSTRATION OF BACTERIAL CULTURES FROM A
CASE OF MYCOTIC ENDOCARDITIS IN MAN AND
OF SPECIMENS SHOWING THE EXPERI-
MENTAL PRODUCTION OF THE
DISEASE IN RABBITS.

The communication was a preliminary one, the experiments not having yet been completed. For some years the presence of bacteria has occasionally been observed in the cardiac and peripheral lesions of malignant ulcerative endocarditis. It has, however, been found that not only, not in all cases of acute vegetative endocarditis, but not even all cases of ulcerative endocarditis present bacteria in their lesions. The speaker thought that the anatomical distinction was not clearly enough drawn between simple and

malignant ulcerative endocarditis. Of eleven cases of well marked ulceration of the valves, which he had studied within the past four years, only four showed the presence of bacteria. In only one case of malignant ulcerative endocarditis was he able to isolate and study the living bacteria. This was a case of pyæmia following cuneiform osteotomy for club foot. The tests applied showed the bacterium to be the staphylococcus pyogenus aureus.

The experiments on animals were then described, and the following conclusions were drawn. If we sum up the results of combined morphological and biological examination of the cases thus far studied, we find that the spherobacteria found in the cardiac and peripheral lesions were the staphylococcus pyogenus and the staphylococcus pyogenus aureus and albus, either alone or together.

The intravenous injection of either of these or a mixture of them into the rabbit after mechanical or chemical injury of the endocardium is capable of inducing lesions strictly analogous, if not identical with those found in malignant ulcerative endocarditis in man. The coccus sepsis of nicolain is capable of producing similar results. Neither the endocardial injury nor the intravenous injection of bacteria alone are sufficient to induce the cardiac lesion. Both are necessary.

As far as the observations go, they tend to confirm the view that malignant ulcerative endocarditis is simply one of the forms of pyæmic lesion determined by the predisposing conditions of the endocardium. Whether or not there are other forms of the disease induced by other species of bacteria or having no relation to bacteria at all, are questions which are more likely to be settled by experiment than by conjecture.

FRIDAY, MAY 18—SECOND DAY.

MORNING SESSION.

DR. W. T. COUNCILMAN, of Baltimore, read a paper on

CERTAIN ELEMENTS FOUND IN THE BLOOD OF
MALARIAL FEVER.

It has long been known that changes in the blood occur in this disease. It is now known that in the red corpuscles there are certain bodies which appear to be living organisms, and these occur only in this disease. These are found by taking a drop of blood and spreading it on a slide so that there shall be but a single layer of corpuscles. These are stained with a weak solution of fuchsin, and examined with a high power. The nuclei of the white corpuscles will be intensely stained, the red slightly stained, and in some of the red corpuscles will be seen brightly stained bodies of irregular shape. These exhibit distinct amoeboid movements. The variety of their changes of form was illustrated by drawings. Certain hyaline bodies are also found and were described. The speaker then referred to the work of other investigators in this field. And gave a review of the results which they had obtained.

DR. HENRY M. LYMAN, of Chicago, read a paper on
TETANY.

Tetany may be defined as a more or less general

ized, intermittent, usually tonic convulsion of the muscles of the limbs and trunk; sometimes involving the face and visceral organs, usually painful, but never attended with loss of consciousness. The disorder is functional, and is based upon no distinctive pathological lesions of the central nervous organs. It is manifested in a series of attacks which occur at intervals varying in length from a few hours to weeks or even months. These attacks are sometimes very abrupt in their onset; oftentimes they are preceded by headache, disturbances of the digestive organs, and various orders of sensation in the skin and muscles, after which the characteristic paroxysms appear. During the paroxysms the flexor muscles are usually the seat of contracture, but sometimes the extensor muscles of the limb are principally involved, so that the fingers and toes may be spread apart and extended. Sometimes the flexor muscles about the elbow are principally involved. Single muscles alone may be attacked. These contractions may be very energetically developed with considerable pain, or they may be sluggish and painless. The pain is usually due to the muscular spasm, but neuralgia may be associated with the cramp and the skin may sometimes become inordinately sensitive. The pain may at other times become located about the joints, which then present the characteristic appearance of rheumatism. Diminished sensibility in certain parts of the body may be sometimes observed during or after an attack. The special senses are rarely disturbed. The action of the heart is seldom changed except by transient palpitations; and only when the respiratory muscles are involved in severe cases is there any difficulty in breathing. A febrile movement is only remarked when inflammatory complications are present. Electrical tests indicate an increased excitability of the motor nerves which may sometimes even include the facial nerves.

The disease is rarely fatal, although death has occasionally resulted from prolonged spasm of the respiratory muscles. The duration of the disorder is quite variable and relapses are rather frequent.

Having no relation with any particular lesion of the nervous centres, tetany appears to be dependent upon a functional instability of the nervous and muscular organs. This instability is usually the result of diseases that affect the organs of digestion and the processes of nutrition. Congenital weakness, and the period of debility that precedes or follows any acute disease may then afford occasion for the manifestation of this particular disorder.

The principal diseases with which tetany may be confounded are, tetanus, organic diseases of the brain and spinal cord attended with contracture, epilepsy, especially the so-called cortical or Jacksonian variety, professional cramp and spasmodic phenomena of ergotism.

The treatment must be directed in a general way against the fundamental instability of the individual constitution. Mild attacks require no special therapy, but severe attacks often demand the energetic use of narcotics and anæsthetics for their relief.

DR. JOHN T. CARPENTER, of Pottsville, referred to the association of tetany with septic poison. He

described a case in which this association was quite distinct, and in studying his cases of tetany, particularly of the milder variety, he thought that he was able to trace them to septicaemia.

DR. A. JACOBI thought that in a large number of these cases there was reason to believe that there was meningeal hyperæmia. An occasional cause which has not been mentioned, is masturbation; this he had seen in one case in which the attacks always followed masturbation, and had not occurred before the age of puberty.

DR. REGINALD H. FITZ, of Boston, read a paper on

PERFORATING INFLAMMATION OF THE VERMIFORM
APPENDIX; WITH SPECIAL REFERENCE TO ITS
EARLY DIAGNOSIS AND TREATMENT.

The paper was based upon an analysis of 257 cases of unquestionable perforating ulcer of the appendix, and of 209 cases diagnosticated as typhilitis, perityphilitis and perityphilitic abscess. In the latter series the diagnosis was clinical not anatomical.

The important features in the etiology of appendicitis were considered also the limitations as to sex and age. It was found that the disease occurred most frequently among previously healthy youths and young adults, especially males, that a fecal concretion or foreign body was present as a local cause in more than three-fifths of the cases. Attacks of indigestion and acts of violence, especially when indirect, were exciting causes in one-fifth of the cases. The action of these causes was favored by a constipated habit, or by congenital or acquired irregularities in the position and attachment of the appendix.

The first characteristic symptom of a perforating appendicitis was found to be a sudden severe abdominal pain. This occurred in eighty-four per cent. of the cases, and usually in the right iliac fossa, where tenderness could always be found, even when the pain was referred to some other locality. The pain was attributed to the actual perforation or the detachment of fresh adhesions.

Fever was the next characteristic symptom and occurred in the course of twenty-four hours. Finally came the swelling which made its appearance in the course of three days.

The chief source of danger from the appendicular peritonitis arose from its becoming generalized. Such a result followed most frequently between the second and fourth days. More than two-thirds of the patients died during the first eight days, and two-thirds of these between the fourth and eighth days inclusive.

The question of a differential diagnosis was then discussed. The determination in resolution was referred to. It was considered to take place in about one-third of the cases as approximately determined from the recorded cases of typhilitis and perityphilitis. Even resolution might be undesirable, since the number of cases of recurrent disease is considerable and might have been prevented by appropriate treatment.

The reader recommended at the outset the opium treatment with rest and a liquid diet, the food being given in small quantities, frequently repeated. If it became evident that general peritonitis was imminent at the end of twenty-four hours after the sudden in-

tense pain, the appendix should be exposed and removed. Usually the symptoms were not so urgent that the appearance of the swelling could not be awaited. Although Willard Parkes advised that the abscess might be opened as early as the fifth day, the practice has been to operate at a later date; 47 per cent. of the cases were operated upon in the second week and 26 per cent. after the third week.

More favorable results in the future were to follow the earliest possible opening of the swelling. This in most instances was at the outset a sac formed by a circumscribed peritonitis. It was usually present on the third day of the disease, dating from the pain, its first marked, characteristic symptom. Negative results from a diagnostic puncture did not contraindicate the operation.

DR. WILLIAM PEPPER related two cases which bear upon this point. On Saturday last, while making a post-mortem examination for another purpose, he examined the appendix. The appendix contained two hard concretions looking like date seeds and some hardened feces. These must have been there for a long time, but there were no evidences of inflammation.

A few days before that, he made a post-mortem examination in the case of a man aged 40, who had for years sacrificed every interest in life for his business. On Monday he had some nausea and vomiting, for which he took a laxative. He returned to his home in the evening feeling badly and sent for a physician. There was vomiting; some fever. There was marked abdominal pain, which was relieved by the use of opium suppositories. On the fourth day the speaker examined him, but could detect no tumor in the right iliac region. There was frequent and free micturition. This symptom would have a bearing upon the possible existence of intestinal obstruction. Another marked symptom was tenesmus. Several large stools had followed the laxative. Enemas of warm oil produced no evacuation. Rectal examination gave a sense of indistinct fulness, but showed no hard tumor. Collapse set in on the fifth day and the patient died on the seventh day.

The question of laparotomy was carefully discussed. It was not performed at first because of the uncertainty of the diagnosis, and later, when the diagnosis became evident, because of the symptoms of collapse. At the autopsy no peritonitis was found. There was a contraction of the ascending colon at its junction with the transverse colon, but not sufficient to cause complete obstruction. A circumscribed abscess was found around the vermiform appendix, which was dilated. There was a large perforation, but no obstruction was found.

These cases have impressed upon him the view that perforation of the appendix is only the explosion of an old catarrhal appendicitis, and that it is not an acute idiopathic affection.

The diagnosis in these cases is a matter of great difficulty in the early days, except where it is associated with considerable pericæcal inflammation.

He agreed with Dr. Fitz, that early operation gives the only chance of saving the patient. He did not think the third day too soon. The difficulty is to

arrive at a sufficiently clear diagnosis at that early day to justify laparotomy as an exploratory operation.

DR. J. T. DANA, of Portland, Me., thought that it is not rare to find inflammation of the appendix as a latent affection. In a case which he recently saw, the first symptom was the occurrence of general peritonitis. By exclusion he made the probable diagnosis of perforation of the vermiform appendix. The case resulted fatally in seventy-two hours. At the autopsy general peritonitis was found, and there was an opening in the appendix through which a concretion had escaped. A second body was found within the appendix. There had been no previous symptoms to call attention to disease of the appendix. This illustrates a class of cases of which he has seen not a few.

DR. A. L. LOOMIS said that from his experience, he thought that it was impossible in the majority of cases to make an early diagnosis by the ordinary means of diagnosis. Of the symptoms given by the patient the most certain indication seems to be given by the occurrence of a chill. When pain is marked it will usually be localized in the left side, but not necessarily. Recognizing the importance of the early diagnosis, he had decided several years ago in such cases to put the patient under the influence of an anæsthetic and examine by the rectum and externally. In the first case that he adopted this plan, the chilly sensation had preceded his visit twenty-four hours. By bimanual palpation he satisfied himself that there was an increase in the region of the appendix, and expressed the opinion that perforation had occurred and recommended operation. This was refused. Peritonitis set in within twenty-four hours and the patient died. In two other cases he made the diagnosis by the same plan. It must be remembered that the vermiform appendix does not occupy the same position in all individuals.

As soon as the diagnosis of perforation is made out, the operation should be performed.

DR. E. G. JANEWAY, of New York, remarked that these cases of appendix disease may be divided into three classes. In one an inflammatory process of the cellular tissue, with or without the formation of pus, is established. This may go on to recovery. If pus forms, surgical procedures should be resorted to. In another class of cases there is a circumscribed collection of pus in the peritoneal cavity. In this class operation should be resorted to.

DR. WILLIAM M. POLK, of New York, read a paper on

PERI-UTERINE INFLAMMATION.

The purpose of the paper was to consider those masses found about the roof of the vagina, generally to the sides of the uterus, sometimes behind, rarely in front. These have been described under the head of pelvic cellulitis and peritonitis, and have been the cause of much controversy. The speaker considered these masses to be the result of salpingitis due to uterine disease. Under ordinary circumstances the disease travels by way of the tubes, but in septicæmia it travels by all routes. Fifteen cases were re-

ported in which the symptoms and signs ordinarily ascribed to pelvic cellulitis and peritonitis were present, but in which opening of the abdomen showed salpingitis, peritonitis and ovaritis, there being no thickening of the cellular tissue. Except in those cases in which there was shortening of the ligaments, the uterus presented about the normal mobility. Pelvic abscess, in the writer's opinion, was in the majority of cases of tubal origin.

As regards the causation of these masses, anything that will produce endometritis may produce salpingitis and cause these masses.

Prognosis.—Death is the exception. This result is to be expected when septicæmia is the cause of the trouble, or when there is a depraved state of the system. The occurrence of abscess is usually followed by recovery. If the mass remains the permanent cure of the case is doubtful.

In chronic cases, after all other measures have failed operation may be performed. The tubes need not necessarily be removed. The tearing of the adhesions may be sufficient.

Conclusions.—Salpingitis is neither a new nor a rare disease. It is, with peritonitis, the most common form of inflammation about the uterus, holding in point of frequency almost the same relation to the extra-uterine surface as does endometritis to the intra-uterine.

The majority of cases get well. A small number do not get well, and these are capable of causing such danger and distress to the patient that abdominal section and removal of the tubes and ovaries is a necessity.

DR. W. H. WELCH, of Baltimore, read a paper on
AN EXPERIMENTAL STUDY OF GLOMERULO-NEPHRITIS.

Of the various processes which make up the pathological anatomy of Bright's disease, the two which at present awaken the greatest interest and the study of which promises the most fruitful results, are probably the changes which take place in the glomeruli and atrophy and necrosis of the epithelial cells.

The questions which have not as yet received full and satisfactory answers are, What is the origin of cells which often in nephritis occupy the space between the glomeruli and the capsule of Bowman? Does migration of the white corpuscles or diapedesis of the red corpuscles take place through the glomerular capillaries? What relation as to frequency and intensity do changes in the glomeruli play in the pathology of Bright's disease? In expectation that light might be thrown upon these questions, the speaker had experimented on rabbits and white mice, by the production of acute cantharadial poison. A concentrated solution of cantharadin in acetic ether was employed by subcutaneous injection. After a toxic dose, the urine diminishes and is finally suppressed. It contains albumen, hyaline casts, and a large number of leucocytes and red blood corpuscles.

Microscopical examination of the kidney in mice shows here and there foci of infiltration with small round cells, doubtless migrated white blood corpuscles. The epithelium of the convoluted tubes is in places normal in appearance; in other places it is

swollen and often the inner part of the cells is broken off, appearing as a granular mass in the lumen of the tube. The most marked change is found in the malpighian bodies. In the greater number of these, there is between the glomerulus and Bowman's capsule a wide space, partly or wholly filled with cells. These are larger than white blood corpuscles. They are frequently arranged in a crescentic mass. These appearances are similar to those described in glomerulo-nephritis in man. In the latter case these cells are attributed to the swelling and desquamation of either the capsular or glomerular epithelium. Such explanation does not hold in the present case. The epithelium of the capsule is often intact and the glomerular epithelium may retain its normal position. More frequently it is swollen and may desquamate. There are no appearances which justify the derivation of the greater number of the cells from the epithelium of the glomerulus. These cells can not be regarded as white blood corpuscles changed by the action of the poison, for the cells circulating in the blood are exposed to the same poison. These cells may be derived from the epithelium of the convoluted tubes in immediate communication with the malpighian bodies. The cells in the capsular space are identical with those in the convoluted tubes. At times there can be found groups of cells arranged in the form of a ring, with a central space, just like the epithelium of the uriniferous tubules.

It is difficult to decide whether the cells occluding the glomerular capillaries in acute and chronic Bright's disease are white blood corpuscles or endothelial cells, but the speaker inclined to the view that at times they are detached endothelial cells. Swelling of the endothelium and accumulation of cells in the glomerular capillaries appears to be a nearly constant lesion in the acute nephritis of scarlet fever. In one case examined this was almost the only lesion in the kidney. Occasionally pathologists meet with kidneys in which the apparent changes do not explain the symptoms. In such cases careful examination of the glomerular capillaries should be made. It is difficult to think of any lesion of the kidney more destructive to its function than occlusion of the capillaries.

While disposed to attach much importance to the changes in the glomerular capillaries, we are not justified in asserting that these changes constitute the primary and essential cause of Bright's disease. They are co-ordinate with other lesions.

He suggested that instead of the term glomerulo-nephritis, the term glomerulitis be used. The form characterized by accumulation of the cells between the glomerulus and Bowman's capsule may be designated desquamative glomerulitis, and that characterized by the accumulation of cells or by other changes within the capillaries may be called intra-capillary glomerulitis.

DR. WM. OSLER, of Philadelphia, read a paper on
BICUSPID CONDITION OF THE SEMILUNAR VALVES AND ITS RELATION TO AORTIC VALVE DISEASE.

A bicuspid condition may be said to exist when two of the three sigmoid cusps have more or less

perfectly fused so that the arterial orifice is guarded by only two segments. The points alluded to were: *First.* The frequency of the condition. The abnormality is a well-recognized one. Dilga recently collected the statistics, and has found sixty-four cases of this condition in the pulmonary artery, and twenty-three in the aorta. This statement gives an incorrect idea of its frequency in the latter vessel. In over eight hundred autopsies at the Montreal General Hospital there were eighteen cases, seventeen in the aortic valves alone, and in one pulmonary and aortic segments were both involved. In one hundred and ten cases of valvular disease of all kinds, there were fifty-seven in which the aortic valves were affected, so that this condition existed in over thirty per cent. of all cases of aortic valve disease.

Second. The clinical history. The part played by this condition in aortic valve disease is illustrated by the history of the eighteen cases. Two died suddenly from cardiac syncope. Twelve presented the pictures of chronic aortic insufficiency, and in four the lesion was accidentally found, death having resulted from other causes. In sixteen cases there was hypertrophy of the heart, chiefly of the left ventricle. With the exception of one case, a foetus at the eighth month, the patients were adults. The ages ranged from 20 to 60 years. This contrasts in a marked manner with the history of this defect in the pulmonary artery. A great majority of the instances present other serious anomalies of development, and death takes place before puberty.

Third. The mode of origin of the lesion. Unquestionably the majority of the cases are congenital, and result either from faulty development or a foecal endocarditis. The former view seems the more probable. (a). From the fact of the existence of the condition in foetal life without any traces of endocarditis. (b). The occurrence of all grades of the condition, from fusion of the attached terminal margins of continuous segments to perfect fusion of the cusps with scarcely an indication of the line of union. (c). A comparison between the size of the conjoint and single cusps indicate that the anomaly must take place at a very early period of development, as in some instances the single valve equals or is even larger than the fused segments, while in others the slight inequality in size is scarcely consistent with the view that a foecal endocarditis, subsequent to the formation of the valves, had caused coalescence of the curtains. We do not know accurately the details of the development of the sigmoid valves, but Tonge's interesting observation on the chick that two of the cusps are formed before the third may have some connection with the production of this anomaly.

DR. GEORGE M. STERNBERG, U.S.A., read a paper on

THE BACILLUS OF TYPHOID FEVER.

Recent researches support the view that the bacillus described by Eberth in 1880, bears an etiological relation to enteric fever, although the final proof that such is the case, is still wanting. This proof would consist in the production in one of the lower animals of the specific morbid phenomena, which

characterize the disease as it occurs in man, by inoculation of a pure culture of the bacillus. Thus far we have no evidence that anyone of the lower animals is subject to the disease, as it occurs in man; but Fraenkel and Simmonds have shown that the bacillus of Eberth, is a pathogenic organism, and that pure cultures injected into the peritoneal cavity of mice or into the circulation of rabbits causes the death of these animals, and that colonies of the bacillus are found in the spleen, which resemble in every respect the colonies found in the spleen and other organs of typhoid cases.

The researches of Eberth, Meyer, Gaffky, Fraenkel and others, indicate that this bacillus is constantly present in the intestinal glands, and in the spleen of typhoid cases, and that Gaffky has shown that pure cultures may be obtained from the spleen, even in cases in which a microscopical examination fails to demonstrate the presence of the characteristic colonies. The researches of Brieger show that a toxic ptomaine is produced as a result of the vital activity of Eberth's bacillus, when it is cultivated in albuminous culture media. This injected into guinea pigs, causes salivation, diarrhoea, debility, dilated pupils, rapid respiration and death at the end of twenty-four or forty-eight hours.

Demonstrated facts relating to the propagation of typhoid fever indicate that it is due to an organism, which is capable of multiplication external to the human body in a variety of organic media at comparatively low temperatures. Eberth's bacillus complies with these conditions. In consideration, therefore of its constant presence and the absence of any other organism as shown by microscopical examination and culture experiments, the inference seems justifiable in the present state of science, that this bacillus bears an etiological relation to the disease in question.

DR. E. C. SEGUIN, of New York, made a

CLINICAL REPORT OF NINE CASES OF HEMIANOPSIA.

He presented an abstract of nine cases of lateral hemianopsia due to cerebral lesion and called attention to the following points of interest: Of the nine cases, five had right lateral hemianopsia, and four left lateral hemianopsia. Three of the cases of right sided hemianopsia presented the following association of symptoms: hemianopsia, right-sided hemiparesis with post-paralytic ataxia and partial hemianæsthesia. Two of these cases also exhibited alexia without other aphasic symptoms. It is interesting to note that all cases of right-sided hemianopsia do not have alexia, and also that post-paralytic ataxia is not always accompanied by hemianopsia, though probably this is more common than is generally supposed. The six other cases were practically cases of pure hemianopsia, *i. e.*, there were no paralytic or sensory symptoms, or aphasia indicating extensive cerebral disease.

In the first category the lesion is probably placed on the outer edge of the thalamus, so as to involve the fasciculus opticus and the posterior division of the internal capsule. In the second category, the lesion is quite certainly further back or in the white

matter of the occipital lobes. In two cases of the second category, marked and increasing weakness of both legs was present, a symptom perhaps due to the upward and forward extension of a tumor toward the paracentral lobule.

A very peculiar symptom in two cases of the second category, and one which the author thinks is new, was the occurrence of hallucinatory images for a short time in the darkened half-field. This is a symptom of irritation, and analogous to the convulsive movements which sometimes precede paralysis of a limb when its motor centre is being destroyed by disease.

Ophthalmoscopic changes were observed in only one case of the second category. In this case, neuro-retinitis developed in both eyes under the physician's observation about one month after the first visit.

In no case was the hemiopic pupillary reaction of Wernicke observed.

A special pathological question came up in one case of the second category. In 1883, the patient had glaucoma with irregular hemiopic defect, first in one eye, and later in the other, and yet only fourteen months later was pure geometric hemianopsia found. Could glaucoma produce this? The speaker thought not; being unable to conceive how an intraocular pressure could so affect the retina and optic nerves as to produce a strictly hemiopic defect in dissimilar halves of each eye. A central lesion is quite certain.

A very puzzling point is the perfection of central vision in these and other cases of central hemianopsia. The vertical line always passes by the point of fixation, no matter on which side the blindness is. We must conclude that the macula is not involved in the loss of function, and the question arises, can the macula have a double innervation from the visual centre? This point the author intends to study thoroughly. The speaker also exhibited specimens illustrating the seat of lesion in certain cases of hemianopsia.

DR. HENRY F. FORMAD, of Philadelphia, exhibited specimens of

CYANOTIC INDURATION OF THE KIDNEYS.

This condition is produced by anything which interferes with the circulation through the kidneys. The shape of the kidney where the induration results from alcoholism is rounded and shortened. The kidney presents a pig-back appearance. Where the cyanotic induration results from heart disease, the shape of the organ is not altered, as the condition takes place gradually.

The following papers were read by title: *Notes of a Case of Hepatico-Bronchial Fistula*, by Dr. J. E. Graham, of Toronto; *Pancreatic Hemorrhage as a Cause of Sudden Death*, by Dr. F. W. Draper, of Boston; *Pernicious Anæmia*, by Dr. A. Jacobi, of New York; *A Case of Hodgkin's Disease*, by Dr. F. Forsheimer, of Cincinnati.

A vote of thanks was tendered the Government officers and the profession of Washington for courtesies extended, and the Association adjourned.

NINTH INTERNATIONAL MEDICAL CONGRESS, TO BE HELD IN WASHINGTON, D. C., COMMENCING SEPT. 5, 1887.

PRELIMINARY ORGANIZATION.

SECTION XIV. PUBLIC AND INTERNATIONAL HYGIENE.

President—JOSEPH JONES, M.D., OF NEW ORLEANS, LA.

Vice-Presidents—John Simon, 40 Kensington Sq., W. London; B. W. Richardson, 25 Manchester Sq., W. London; J. W. Thudicum, 11 Pembroke Garden, W. London; A. N. Bell, Brooklyn, N. Y.; J. N. McCormick, Bowling Green, Ky.; J. Berrien Lindsey, Nashville, Tenn.; J. F. Y. Paine, Galveston, Texas.

Secretaries—Geo. H. Rohé, Baltimore, Md.; Walter Wyman, U. S. Marine Hospital Service.

Council.—Thomas Antisell, Washington, D. C.; Le Baron Botsford, St. Johns, New Brunswick; Henry Carpenter, Lancaster, Pa.; Richard H. Day, Baton Rouge, La.; J. W. Dupui, Baton Rouge, La.; Oscar DeWolf, Chicago, Ill.; Landon B. Edwards, Richmond, Va.; James Finney, New Orleans, La.; Wiley K. Foot, New Orleans, La.; Albert L. Gibson, Washington, D. C.; E. L. B. Godfrey, Camden, N. J.; D. W. Hand, St. Paul, Minn.; Thomas Hébert, New Iberia, La.; Charles H. Hewitt, Red Wing, Minn.; Joseph Holt, New Orleans, La.; Stanhope Jones, New Orleans, La.; Benjamin Lee, Philadelphia, Pa.; Henry Leffman, Philadelphia, Pa.; J. R. Le Monnier, New Orleans, La.; Henry F. Lyster, Detroit, Mich.; A. W. Leighton, New Haven, Conn.; Wm. R. Mandeville, New Orleans, La.; N. R. Milner, New Orleans, La.; H. L. Orme, Los Angeles, Cal.; R. H. Reed, Mansfield, Ohio; W. L. Schenck, Osage City, Kan.; C. M. Smith, Franklin, Ohio; R. M. Swearingen, Austin, Texas; M. K. Taylor, U. S. Army; G. B. Thornton, Memphis, Tenn.; Wm. M. Welsch, Philadelphia, Pa.

SUBJECTS FOR DISCUSSION AND FOR THE PREPARATION OF MONOGRAPHS.

I. Quarantine.

- a. History of quarantine.
- b. Conduct of quarantine stations.
- c. Sanitation of ships.
- d. Sanitation of maritime ports.
- e. Regulation and control by sea and land of such diseases as yellow fever, Asiatic cholera, Oriental plague, Oriental leprosy, typhus and typhoid fevers, small-pox, scarlatina and measles.
- f. The relations of the duration of quarantine as determined by the natural history of various diseases, and more especially by the period of incubation of their specific poisons.
- g. Value of heat (dry heat and heated steam) and steam in the disinfection and cleansing of infected vessels.
- h. Relative value of sulphuric acid and other agents, as carbolic acid, sulphate of iron and bichloride of mercury, in disinfection.
- i. Describe the apparatus for the application of disinfectants.

j. Quarantine should embrace not merely detention, but also thorough cleansing and disinfection. Whenever necessary, the cargo should be discharged and thoroughly aired and fumigated.

k. Structure and conduct of quarantine hospitals.

l. Land quarantine, its value and mode of conduction.

m. The proper structure, ventilation and conduct of railroads so as to prevent the dissemination of contagious and infectious diseases.

n. Shall the General Governments of the civilized world assume control of all the quarantine systems, and by mutual consent reduce the entire subject of quarantine to order and apply the most improved methods of sanitation and disinfection?

o. Shall the Government of the United States assume charge of the entire subject of quarantine and relieve the individual States of the Union of all further responsibility of regulating quarantine either with foreign countries or with each other?

II. Military Hygiene.

a. Food of the soldier.

b. Clothing of the soldier.

c. Exercise of rest: effects of infantry, cavalry, artillery and bicycle exercise upon the soldier.

d. Shelter. Structure of tents.

e. Water supply of armies; method of testing and improving.

f. Military prisoners and military prisons.

g. The establishment of uniform rules to be recognized by all civilized nations for the treatment, food and clothing of military prisoners, and for the regular and continuous exchange of all military prisoners.

h. Hygienic arrangements of field and general hospitals.

III. Naval Hygiene.

IV. Structure and Arrangement of Prisons and Treatment of Prisoners.

a. Treatment of prisoners: food, clothing and occupation.

b. Has the State the right to work prisoners in swamps and marshes and cause the destruction of human life by the neglect of all the laws of hygiene?

c. Are not deaths occasioned amongst prisoners by cruelty, overwork, scant clothing, poor food, directly chargeable against the officials composing the government, whether acting in behalf of a city, county, State or Government?

V. Structure, Hygienic Arrangements and Ventilation of Buildings.

a. Proper condition of the soil for the location of buildings.

b. Relations of building material to moisture and to fire.

c. Public buildings: legislative halls, depots, churches, etc.

d. School-houses and colleges.

e. Factories.

f. Dwellings.

VI. Influence of Agriculture on Public Health.

a. Influence of overflows on the public health.

b. Importance of drainage; clearance of swamps, marshes and land generally.

c. Influence of the cultivation of rice on the public health.

d. Influence of cotton, tobacco and sugar, and indigo culture on the public health.

VII. Food and Its Adulterations.

a. Influence of different methods of preserving food on the public health.

b. Influence of canned food upon the public health.

c. The injurious effects of lead, copper, tin, zinc, antimony, etc., upon food; said metals being used for culinary vessels, dishes and receptacles.

VIII. Relations of Water to the Public Health.

a. Properties of wholesome potable water.

b. Water supplies of cities.

c. Proper supply to each inhabitant, etc. Transmission of disease germs through the medium of water.

IX. The Influence of Alcohol upon the Public Health.

a. Wine.

b. Malt liquors.

c. Distilled liquors.

X. Influence of Narcotics upon the Public Health.

a. Tobacco.

b. Cannabis indicus.

c. Opium and its preparations.

d. Chloral hydrate, chloroform and ether.

XI. Influence of the Electric Light upon the Public Health.

XII. Influence of the Modern Modes of Travel upon the Public Health.

a. Effects of railroad travel in inducing paralysis.

b. Hygienic structure and conduct of railroad trains so as to avoid the introduction and dissemination of infectious and contagious diseases.

c. Structure and arrangement of sailing and steam ships.

d. Hygienic regulations of officers, crews and passengers.

XIII. Relations of Filth to Public Health.

a. Relative merits of the various plans of sewerage and of the disposal of garbage and fecal matter.

b. Organization of the scavenger force.

c. Best method of disposing of the dead.

d. Effects of putrefaction in the dissemination of the disease germs of contagious and infectious diseases such as cholera, yellow fever, small-pox, measles, scarlet fever, etc.

e. Cremation.

XIV. Relations of Disease-Germs to the Origin and Spread of Contagious and Infectious Diseases and to Endemic and Epidemic Diseases.

a. Relations of malaria to the public health.

b. Nature of the malarial poison.

c. Physical, chemical and microscopical characters of the poison or cause of the following diseases: Yellow fever, typhoid fever, typhus fever, relapsing fever, measles, scarlatina, syphilis, phthisis, Oriental leprosy, elephantiasis, small-pox.

d. Relations of phthisis to the public health.

- e. Relations of syphilis to the public health.
- f. Measures for the arrest of small-pox.
- g. Value of cow-pox vaccination.
- h. Accidents attending vaccination. Transmission of the syphilitic virus through the medium of the vaccine virus.

Authors desiring to contribute to the Fourteenth Section of the Ninth International Medical Congress should commence their labors at the earliest practicable moment and communicate with

JOSEPH JONES, M.D.,

Post Office Box 1500, New Orleans, La.

40 KENSINGTON SQUARE, W. LONDON, JUNE 8, 1886.

My Dear Sir:—I feel myself highly flattered by the invitation, with which you honor me, that I should be one of the Vice-Presidents of Section XIV of the International Medical Congress about to be held in Washington.

To my very great regret, I have no hope that it will be in my power to attend the Congress; and I feel doubtful whether, in that state of the case, you will still think me qualified for the honor you so kindly propose. This I can only leave to your judgment; subject to which, my answer to your very flattering invitation would of course be, that I should be proud to hold, under your Presidency, any honoring post for which you may deem me fit.

Meanwhile, and at any rate, permit me to offer you, from this side of the Atlantic, my heartiest good wishes for the success of the Congress in general, and of Section XIV in particular; and believe me, dear sir, with much respect,

Your obliged faithful servant,

JOHN SIMON.

Professor Joseph Jones, M.D., 156 Washington Ave., New Orleans, La.

11 PEMBROKE GARDEN, W. LONDON, JUNE 9, 1886.

JOSEPH JONES, M.D., NEW ORLEANS:

My Dear Sir:—I have the honor to acknowledge the receipt of your letter of May 17 ultimo, in which you express to me your wish that I should be appointed a Vice-President of the Fourteenth Section of the Ninth International Medical Congress, to be held at Washington in 1887.

In reply I have pleasure in informing you that I shall consider it a great honor to fill this office, which will be so worthily presided over by yourself. I sincerely hope that circumstances will permit me to visit America, and to make your personal acquaintance. Yours most faithfully,

J. W. THUDICUM, M.D.

25 MANCHESTER SQUARE, W. LONDON, JUNE 7, 1886.

My Dear Sir:—It will give me the greatest pleasure to accept the office of a Vice-President of the Section on Public and International Hygiene of the International Medical Congress to be held at Washington in September, 1887.

I do not know whether this intimation should be sent to you direct or to some other officer. I therefore send it to you direct with the request that you will send it to the right quarter.

Yours always truly,

B. W. RICHARDSON.

Professor Joseph Jones, M.D., Post Office Box 1500, New Orleans, U. S. A.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of

Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Causes of Sterility—The Pancreatic Juice—Horny Tumor of the Scalp—The Abuse of Carbolic Acid—M. Chevreul.

In a clinical lecture recently delivered by Professor Pajot, he stated that among the causes of sterility uterine catarrh is about the most common. Next in the order of frequency may be mentioned the narrowness of the os uteri and the peculiar conical form of its cervix, which is almost characteristic of the sterile condition. When, however, the external orifice of the neck is cup-shaped, which gives the sensation to the touch of a small depression produced by a lentil imbedded in potter's clay, the affection in this condition is curable. Another cause of sterility in women is attributed to uterine displacements, which have often been, and still are, turned to profitable account by quacks, and unfortunately, also by medical men who prefer their own interests to those of science. Uterine displacements are divided into two great classes: versions, or deviations, and flexions. The former constitute obstacles almost insurmountable to fecundation, whereas the latter are not always so.

Here is a case in point: "About two years after the war I received a visit from an Austrian lady who came to consult me. On examination I found that she had an extreme retroflexion, for which she had consulted nearly all the doctors in the world, and they all, except Scanzoni, had declared that under the circumstances pregnancy was impossible. She menstruated regularly and without pain. I told her that if the menses could pass out other things could pass in, and that her displacement was not a hopeless obstacle to conception. A week after I saw her she became pregnant, and was subsequently confined naturally, after which I kept her in bed till her menses reappeared (three months), and succeeded in producing a perfectly straight uterus, of which I was very proud. A year later the displacement was as bad as ever, but that did not prevent her from having two or three more children. This fact proves that those who wish to employ great measures are in the wrong by wishing to replace the uterus to its normal position by means of special instruments. This is all useless; the best replacer of the uterus is pregnancy. A displacement cannot be considered as a disease; it is an infirmity, and moreover, an infirmity easy to be borne. It is said that this affection causes great inconveniences to women. For my part, I declare that if women had not been told by the doctor or midwife of the existence of such an

infirmity, they would never suspect it, so little does it inconvenience them. During pregnancy, however, this condition might constitute a grave position. A uterine displacement, when it is not exaggerated, causes no annoyance. It is only in cases of considerable descent, which weighs heavily and drags, that a displacement becomes a real inconvenience. The displacement is, in this case, a real obstacle to fecundation, but this is not an insurmountable obstacle.

"In lateral versions or deviations, the neck of the womb may be closed by the walls of the vagina. It is necessary to be aware of this circumstance, so that the existence of sterility in a woman the subject of such a condition would cause no surprise."

At a recent meeting of the Academy of Sciences Professor Chatin read, for M. Defresne, a well-known pharmacist, a work on the "Pancreatic Juice." In this work the author explains what becomes of this juice when introduced into the stomach at the commencement of a repast, when the acidity of the gastric juice is then the result of the hydrochloric acid which it contains. The new researches of M. Defresne have authorized him to express this opinion, viz.: that the pancreatic juice, when introduced into the gastric juice at the commencement of a repast, passes into the state of zymogen in the circulation, and is afterwards separated by the liver, the parotid glands, and the spleen. In the liver it becomes a hepatic zymosis, capable of saccharifying glycogen; in the parotids, a ptyalic zymosis, capable of saccharifying starch in the mouth; and in the spleen, a zymosis which, transmitted to the pancreas, communicates to the juice of this gland the property of saccharifying starch in the duodenum. These experiments demonstrate the good results which may be obtained by administering pancreatine by the stomach.

At the Academy of Medicine Dr. Vidal recently made a communication on the part of Dr. Dubrandy, of Hyères, in which the author relates a curious case of a horny production of the scalp in the human subject. This horn, remarkable for its size, twisted in a spiral form like the horn of a deer, measured 21 centimetres, or about 8¼ inches, in length, and 6 centimetres, or about 2⅓ inches, in circumference; it is cylindrical, of a deep red color, and its surface is striated and furrowed. This singular production appeared, at the age of 40, in a woman who was very stout, weighing 95 kilogrammes, or about 209½ pounds, and in eleven years, that is to say, to the day of her death, the horn had acquired the dimensions related above.

In a paper by Dr. Léon Gautier, on the "Abuse of Carbolic Acid," the author, in citing a note on the subject in a Swiss medical review, states that several cases have come under his own observation of irritation produced by solutions of carbolic acid, even when largely diluted. Varicose ulcers, furuncles, phlegmonous inflammations are aggravated by phenic acid dressings. Even in traumatism, when the wound is not simple, when the skin is more or less profoundly contused in its neighborhood, these applications may also be very injurious. Dr. Gautier concludes his paper with the recommendation that carbolic acid ought to be proscribed whenever the

skin is inflamed or contused; its use should be reserved to simple wounds, even those of operative wounds effected in healthy tissue.

In the event of the death of a distinguished member of the Academies or of other learned bodies, it is customary, at their first meeting after the occurrence, for the president to pronounce a eulogy on the deceased member and at once dismiss the assembly without further proceedings, as a mark of respect to the departed. A curious contrast to this manifestation of mourning took place at the meeting of the Academy of Sciences last week, when the President took the opportunity of congratulating M. Chevreul, the eminent chemist, on his attaining his 100th year, which, however, he only completes in August next; but in consequence of the probable absence of many of the members during that month, it has been thought fit to anticipate the event. The President, in addressing the illustrious centenarian (the members standing) presented him with a magnificent statue in bronze, representing "Study and Meditation," by M. Paul Dubois, the well-known sculptor, who, in designing the statue, took M. Chevreul himself as a model. A soon as the presentation was made—which was accompanied by a bronze medal bearing his effigy to commemorate the event—the proceedings of the meeting were at once closed, in compliment to the venerable academician, as such a circumstance had never been known in the annals of the Institute. M. Chevreul has been sixty years a member of the Academy of Sciences, he having been elected in 1826, and it will be remembered that ten years ago he was presented with a gold medal bearing his effigy, to commemorate the fiftieth year of his academical career.

A. B.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Special Meeting of the Fifth District Branch—Galvano-Cautery in Genito-urinary Diseases—An Excursion to the Catskills.

All who were privileged to attend the recent special meeting of the Fifth District Branch of the New York State Medical Association will long retain the pleasantest memories of that festal occasion. In the morning a meeting of the Executive Committee was held at the rooms of the Young Men's Christian Association at Rondout, on the Hudson, which is now a part of the ancient city of Kingston, with which it is continuous; and afterwards the Fellows, invigorated for the labors of the day by a substantial mid-day dinner at the Mansion House near by.

In the afternoon the scientific proceedings were opened by a paper by Dr. Wm. B. Eager, of Middletown, Orange county, entitled "*Inquiry as to the Cause of Death Following Confinement, on the Sixth Day, with Singular Nervous Symptoms*;" after which Dr. Robert Newman, of New York, gave a demonstration of a new instrument for galvano-cautery in

diseases of the prostate, bladder and urethra. Dr. J. W. S. Gouley, of New York, expressed himself as entirely opposed to the methods of treatment proposed by Dr. Newman. But, however skeptical he might be, he said, he was certainly open to conviction whenever their utility had been demonstrated to his satisfaction.

Later in the afternoon the company took the cars of the Ulster and Delaware Railroad *en route* for the Hotel Kaaterskill, and with them were quite a large number of ladies, who added no little to the pleasure of this most delightful trip. After leaving Kingston there is a charming view of the mountains on the right, and in the course of a few miles the road enters, at Shokan, the great Shandaken Valley, which is of very considerable width at first, but gradually becomes narrower and increasingly picturesque as one advances into it. Not the least of its attractions is the romantic Esopus River, the course of whose clear-flowing and babbling waters the road follows for many miles; while on either hand loom up the grand old mountains, affording at every turn some new and beautiful prospect. At Phoenicia the party changed cars for the Stony Clove Railroad.

While it does not compare in boldness and grandeur with either the Kaaterskill or the Plaaterkill Clove, Stony Clove has always been one of the noted features of the Catskills, and in former years it was a favorite resort of the disciples of Izaak Walton, who had many an incredible tale to tell of their trout-ing adventures, and who doubtless now consider the construction of a railway through the midst of their sequestered haunts as nothing short of sacrilege. The writer well remembers a pleasant tramp that he once had, long before the railroad was built here, through Mink Hollow, the next notch to the eastward, and across the mountains to Stony Clove. At one point between the two Cloves the view was of most varied and imposing beauty. To the extreme left loomed the vast Overlook Mountain, from this direction appearing to taper to quite a sharp point, and, very near the lofty summit, the Overlook House, glistening in the sunshine. Next came some smaller spurs of the Catskills, above which we saw the broad valley of the Hudson, the shining river itself, and the hazy Berkshires beyond. A little farther to the right was Lake Hill, round and shapely, with its placid sheet of water at its foot, mirroring the fair blue skies; while directly opposite, in the very centre of the landscape, stood Mount Tobias, the most conical peak in all the Catskills, majestic and solitary, no other mountains being in its immediate vicinity. Next came a group of the mighty Shandohens, among which could be seen Cornell, the Wittenberg, and the great Slide Mountain, the monarch of the range, all clustered together and looking very blue and beautiful at this distance, with outlines so soft and fair that one might readily fancy them the Delectable Mountains, as they appeared to the eye of weary Christian in his toilsome journey. Coming around, in one grand sweep, to the extreme right, we reach the Catskills again, green and near at hand; while immediately behind us towers to a sublime height a huge peak of old Oldabark Mountain, like a great

sentinel watching with solemn presence over the whole.

Not long after leaving this enchanting spot we entered the woods, and in almost an hour came down into a Clove which we supposed to be the one we desired. To make sure, we inquired at the first house we came to, and were duly informed that we were on the Stony Clove road. After passing the next house, which was about two miles distant, we plunged into the forest primeval, and the track became more and more overgrown as we proceeded. A wild torrent roared now on one side and now on the other of our path, which became steeper and steeper; and, the scenery growing wilder and wilder at every step, we began to doubt very seriously whether we were in Stony Clove at all. It was some time before any outlook could be obtained, but when we did succeed in this the fact became developed that we were down in a deep gorge between two immense mountains, and that a vast wall towered directly in front of us.

Thinking that we should probably have to spend the night in the woods if we entered much further, we concluded to retrace our steps for two or three miles, till we came to the last house we had passed; and having arrived there, we found a lad to whom we stated we were in considerable doubt as to just where we were at that particular time. To our interrogatory, "*ubi terrarum sumas?*" (which, however, we addressed to him in the vernacular), the ingenuous youth, evidently without any intention whatever of being facetious, replied that this was Greene county. Well, that was encouraging, to be sure, as we supposed that we were still in Ulster county; but, at the same time, the information was scarcely definite enough to be of much practical service. Further questioning, however, elicited the fact that we had been up "Warner's Hill;" and when we inquired where in creation, then, the Stony Clove was, our informant said, pointing to a huge elevation on our right, "On the other side of that mountain." At this statement our hearts went down into our boots, as we thought of a weary tramp of five or ten miles to get around the mountain; but we were quickly reassured when he told us that there was a path through a notch which he pointed out. Taking this, we came out, after a couple of miles' walk through the woods, much to our delight, at Martin's saw-mill in Stony Clove.

As we had to go on a mile further before we could get dinner, it was more than half-past four when we sat down to that meal, and by this time it may well be imagined that our appetites had become sufficiently ravenous. Just as we finished our repast, one of the large chair-wagons which one is apt to meet on the roads in this part of the Catskills, came along, and as we replied in the affirmative to the driver's inquiry, "Be you a goin' through Hunter Notch?" he very kindly offered to give us a lift. We thus rode with him for about three miles, when he turned off to go to Hunter village, whither he was returning with his empty wagon, after taking a load of chairs to Phoenicia.

NECROLOGY.

GEORGE SUTTON, M.D.

GEORGE SUTTON, M.D., of Aurora, Indiana, was born in London, England, June 16, 1812, died at his residence, overlooking the town of Aurora, Indiana, June 13, 1886. In 1819, his parents with their children, emigrated to America and settled at Cincinnati, Ohio, but in the spring of the following year removed to a farm on the White Water in Franklin county, Indiana. Here the subject of this notice grew up as a farmer's son, and received his preliminary education in the country log school house, then common in the new States. His first great sorrow was the death of his mother, which occurred in 1827. In 1828 he was sent to Miami University where he obtained a more thorough knowledge of mathematics and the languages than he had been able to get from any of his previous teachers. We are not informed if he graduated, but his knowledge of the languages was good. In 1832 his father returned to Cincinnati, and the same year he began the study of medicine under Dr. Jesse Smith, who a short time afterwards was attacked with cholera and died. He then entered as a private student of Professor John Eberle, and graduated M.D. at the Ohio Medical College in 1836. While studying in Cincinnati he attended a private course of lectures given by Professor S. D. Gross, then of Cincinnati. His graduating thesis was on the "relation between the blood and the vital principle."

On obtaining his degree he began practice in Aurora, where he has labored most successfully and acceptably to the close of his life. In June, 1838, Dr. Sutton was united in marriage to Miss Sarah Folbre, daughter of Charles Folbre, of Aurora. She bore him four sons and a daughter; the daughter and one son alone survives. His wife died in 1868. One of his sons, a promising physician, died in 1877. The doctor was a close observer, a careful and conscientious practitioner devoted to his profession. He was not only well read in his profession, but was learned for his opportunities beyond what would have been expected in the whole range of the sciences. Although diffident he was one of the most entertaining of men in conversation. His character, too, in every respect was of the most honorable. In the fifty years he lived as a physician in Aurora, no man has been more intimately identified with various interests of the citizens of the place than Dr. Sutton. There was no position of honor or trust within their gift which they would not have cheerfully conferred upon him. In 1862 they chose him Mayor of the city by a practically unanimous vote, and reelected him for three times, after which he positively declined to serve as it interfered with his professional duties. When in 1866 cholera threatened to become epidemic, Dr. Sutton was by an almost unanimous voice of the city requested to serve as President of the Board of Health, and was most judicious and active in the means taken to protect the city from the disease. The doctor was a ready and vigorous writer, and early in his professional career began the contribution of articles on medicine to the journals. A paper on "Epidemic

Erysipelas," or "Black Tongue," was published in the *Western Lancet*, Vol. II, 1840. The mere enumeration by title of his many papers would fill pages. A measurably complete list of these may be seen in a sketch of the doctor's life, in a work entitled "Rocky Mountain Medical Association."

Dr. Sutton was never idle, and had trained his rare natural powers for original observation, so as to be constantly in the advanced guard on all the leading questions engaging the medical profession and the scientists of the day. He was also systematic in arranging his observations and giving them freely to the press to assist others. In 1844 he was instrumental in organizing the Dearborn County Medical Society, which for a time met at his house. This Society was reorganized in 1867, and has continued in active and useful operation ever since. He made frequent and valuable contributions to the various societies to which he belonged. His papers, too, have the rare merit of being on live subjects and practical. He was also a member of the Medical Society of the State of Indiana, a constant attendant at its sessions, and its president in 1869. He became a member of the American Medical Association in 1856, attending again in 59, 67, 71, 72, 73, 74, 75, 76, 77, 81, 82, 83, 84 and 85. At the meeting in New Orleans he read an address as the president of the Rocky Mountain Medical Association, in the St. Charles Hotel, on "The Geology of the Globe and its effect upon Vegetable and Animal Life." It was a paper of rare merit and based upon much research and observation, and well worthy of publication. He was a member of the Centennial International Medical Congress which met in Philadelphia, in 1876, the Archeological Association of Indiana, Fellow of the American Association for the Advancement of Science, and an honorary member of the California State Medical Society.

Immediately after the battle of Pittsburgh Landing Dr. Sutton repaired to the scene of the conflict and tendered his professional services, and was assigned to duty on one of the hospital boats. He labored there efficiently until the emergency was passed, when he returned to his home and his larger and more responsible practice. The State of Indiana has reason to be proud of this earnest physician who for over fifty years had discharged, in a highly acceptable manner, the duties of an intelligent and learned physician, an exemplary christian, and an upright citizen.

J. M. T.

MISCELLANEOUS.

HYDROPHOBIA EXPERIMENT.—The first inoculation against hydrophobia ever done in America was performed July 5 by Dr. Valentine Mott, in the Carnegie Laboratory. Dr. Mott's patient was Harold Newell, seven years old, who was bitten by a dog presumably mad June 24. The inoculation was made from a solution of hydrophobic virus obtained by Pasteur himself from the brain of a dog dead from rabies, and transmitted by him through 110 rabbits.

AN ADDRESS IN MEDICINE.

BY JOHN V. SHOEMAKER, M.D.,

OF PHILADELPHIA.

Delivered before the Thirty-seventh Annual Session of the Medical Society of Pennsylvania, held in Williamsport, Pa., June 2, 3, 4, 1886.

MR. PRESIDENT AND GENTLEMEN!—The honor which you conferred in appointing me to prepare the address on medicine for the present session carries with it great labor and serious responsibility. The ideal address on medicine should contain not only a *résumé* of the progress made and the new discoveries announced in the different branches of our science during the previous year, but it should also contain a critical examination of the statements made and the theories advanced in each department of medicine, so that the chaff can be winnowed from the wheat, and our knowledge strengthened by the addition of valuable truths and the rejection of worthless statements and visionary theories. This task, which would not be easy under any circumstances, has been increased to a formidable degree during the past four years by the overgrowth of modern specialism. Indeed specialism has developed in a comparatively short period from the necessary and legitimate consideration of diseases of the eye and ear, and one or two other organs, into a monstrous incubus which casts a shadow over every department of medicine.

It would be the height of folly to deny that all the advances in medicine are the result of clinical observation and experimentation combined with thorough investigation of the functions of the different organs of the body, and the manner in which those functions are modified in health and in disease by various therapeutic agents, but no real addition to our knowledge has been, or can be made by the purblind specialist who attributes all the ills of humanity to a derangement of the organ which he has made his study. He is the bane of modern medicine. The antidote is to let him alone severely. Not understanding or not appreciating the fact that the bond of sympathy, between every organ of the body is so close that when one is affected all of the rest suffer, he contributes little to the general fund of information, but a multitude of words which are intended to magnify himself and mystify his hearers. Emboldened by the tolerance with which he has been received, he has become so arrogant as to assume that the medical wisdom of all the ages is centered in his person, and that he is the master and not merely

the supernumerary of the profession. I trust that this absurd delusion will soon be dispelled and that the practitioners of this State and country will arouse to the necessity of checking the further growth of this excrescence on the body politic.

The thoughtful, reading, busy country practitioner is fully competent to treat and cure any curable affection, and if a cure be impossible, the patient's sufferings can be alleviated, and his life prolonged just as well and as scientifically at home as in New York, Philadelphia, or Boston. The successes of the specialists are heralded to the world; their mistakes and their failures are passed over in silence. No two trees in a forest are of exactly the same size, and there are, and always will be physicians, who are preëminent among the prominent of the profession, but the assertion that there are any diseases which the general practitioner should not attempt to treat is contemptible and untrue. In fact the arrogance of modern specialism is frequently surpassed by its ignorance. It is only a short time ago since one of the most pretentious of New York specialists argued violently that the respiration in croup is slower than normal. Country practitioners who have seen children panting for air, while their respirations rose to 50, 60, 80, and 90 per minute can see from this that overbearing egotism does not always imply intellectual superiority. Many other instances might be referred to, such as exsecting a rib for an imaginary empyema, opening the gall-bladder in search of gall-stones that existed only in the mind of the operator, the barbarous and useless castration of women, and similar outrages. Suffice it to say that the columns of the current medical journals contain ample evidence of the ability of the general practitioner to meet all emergencies, and show that the claim of superior intelligence on the part of the specialist is utterly unfounded. The glory of American medicine does not rest upon the inherited qualities of any one man or set of men, but upon the learning and skill of the medical profession of the entire country.

The most practical observations on medical physiology which have appeared during the year are those of Alexander Harkin, of Belfast, in which he directed attention to the many disorders of the genital organs which are produced by congestion of the medulla oblongata. If Dr. Harkin's admirable observations on this subject were carefully studied by modern gynæcologists the present craze for castrating women would speedily subside. Dr. Harkin has also called attention to the depression of the sympathetic nerv-

ous system in cholera, and the necessity of adopting measures to counteract that depression.

Dr. Isaac Ott, of Easton, Pa., began a series of investigations some time ago to ascertain what relation the nervous system bore to the production of heat and the maintenance of the temperature of the body. These researches are not finished yet, but enough has been ascertained to indicate the existence of heat centres in the cerebrum, and that they are situated in the anterior portion of the optic thalami or in the cortex surrounding the corpora striata.

A curious case reported by M. Tarchanoff is that of a medical student who possesses the power of retarding and accelerating the beats of his heart at will.

Ewald and Boas, of Berlin, have made a series of investigations of the process of digestion; as the result of which they state that stomachic digestion consists of three stages; during the first stage, which lasts half an hour, the gastric juice contains lactic acid; in the second stage, occupying from half an hour to an hour, both lactic and hydrochloric acids are present; during the third stage, consuming an hour or an hour and a half, hydrochloric acid is the only acid present.

The field of bacterial investigation is still being diligently worked, but no very practical results have yet been arrived at. Virchow acknowledges the importance of this subject, but justly deprecates the folly of assigning a bacterial origin to all maladies, and believes that the day of the cells will soon come again. The subject of ptomaines has also received considerable attention. The poison of decaying cheese has been isolated by Dr. Vaughan and termed tyrotoxin.

The theory that the poison of cholera acts primarily on the mucous membrane of the intestinal canal and secondarily upon the sympathetic nervous system has gained many adherents during the past year. The treatment based upon this theory consists in the addition of dilute sulphuric acid to all drinking water as a prophylactic measure, and in the administration in the early stages of the disease of large doses of calomel or ipecachuana in order to produce a free outflow of bile into the intestinal tract, the biliary secretion being destructive to all forms of low organisms. In the second stage the depression of the sympathetic nervous system can be most effectually counteracted by the administration of atropia, strychnia, and capsicum. Dr. Harkin has obtained brilliant results from the application of blisters over the course of the upper portion of the pneumogastric nerve in severe cases of cholera morbus, and earnestly urges a trial of the same measure in true cholera. Dr. W. B. Ryan, of Indiana, has directed the attention of the profession to belladonna or its alkaloid, atropia, in the treatment of cholera infantum. As this disease does not differ materially either in etiology or symptomatology from the cholera morbus, and sporadic cholera of adults, there can be no doubt of the value of belladonna in its management. Dr. Ryan is certainly entitled to our warmest gratitude for presenting the profession with an effective remedy for this dreaded disease of infantile life. The prevention of cholera infantum is of even more importance than its success-

ful treatment. The best prophylactic measure is frequent bathing of the entire surface with cold water. Attention to the diet is also of prime importance, but unless the effects of the excessive summer heat be counteracted by the free use of cold water great mortality will ensue. After an attack of cholera infantum has been fully developed cold bathing will still be found beneficial, and in many cases indispensable.

Dr. J. J. Mulheron, of Detroit, has truly said that "Baths hold an important place in the treatment of the fever of cholera infantum. The soothing influence of a cold bath on a child whose temperature has reached 103° F., and the increased activity of the drugs administered after the bath, need but to be witnessed to make converts to this much neglected remedy in the treatment of cholera infantum. The child should be immersed up to the neck in water at a temperature of 95 F., to which cold water should be added until the bath reaches 70 F. or even lower, the condition of the patient, his temperature, etc., being the guide to the reduction. No hard-and-fast rules can be laid down to govern the temperature of the bath or its frequency; the condition of the infant must be the guide which the good sense of the physician must be trusted to interpret and follow."

Several articles have been published during the past year in reference to the hypodermic use of antipyrin in the treatment of sunstroke or thermic fever. The results do not appear to justify its further employment. Sunstroke can be averted by drinking freely of cold water and avoiding excessive exertion during the heated term. If an attack supervenes the best remedies are free ventilation and the copious external application of cold water. If the pulse be full and bounding, venesection may be resorted to with advantage or aconite may be administered hypodermically.

Dr. H. C. Wood has observed a number of cases of lead poisoning, in which the true nature of the malady was not suspected for a long time, and urges that a careful examination of the urine should be made for lead in all obscure cases of long standing. In connection with this subject it may be stated that Dr. W. S. Janney believes that, in our climate, few, if any cases of cholera morbus occurring in persons not previously debilitated will terminate fatally, and that many of the deaths which are attributed to that disease, are in reality due to the secret administration of a vegetable or a mineral poison.

Dr. Pavy has directed attention to the fact that the presence of albumen in the urine unaccompanied with other symptoms does not necessarily imply a diseased condition of the kidneys. There are many persons whose urine becomes albuminous whenever the blood-pressure is increased as by exercise, mental strain, or a heavy meal, but the albumen disappears in a few hours and the general health remains entirely unaffected. Small quantities of sugar may also appear in the urine occasionally without possessing any special significance.

Several writers in this country and in England have claimed that the relationship between quincy and rheumatism is so close that practically speaking the former may be defined to be a localized rheumatic

inflammation of the tonsils. In proof of this they point to the fact that the majority of cases of quinsy occur during cold, damp weather, and are benefited by the salicylates and alkalies. This argument is ingenious but not convincing. The salicylates and alkalies are beneficial in quinsy because of their sedative and derivative antiphlogistic action, and not because of their antagonism to an imaginary rheumatic etiological factor. Far better results can be obtained moreover by the administration of aconite and guaiac in doses sufficient to produce free diaphoresis and a decided reduction in the force and frequency of the cardiac movements.

Pulmonary syphilis has received considerable attention, but not as much as its frequency and its importance deserve. The principal diagnostic points by which it can be differentiated from pulmonary tuberculosis are the history of a specific infection, the dry, irritating character of the cough, the absence or insignificant character of the râles, the absence or infrequent occurrence of hæmoptysis, the normal appearance of the chest notwithstanding the large area of induration, the substernal tenderness, the thickening of the tibia and clavicles, the absence of bacilli from the sputa, and finally, the absence of severe febrile symptoms; the temperature usually remaining about normal and rarely rising above 101 or 102 until late in the course of the disease. Improvement rapidly follows the internal administration of mercury and potassium iodide. In cerebral syphilis the most effective results can be obtained from mercury used hypodermatically or by inunctions, as by either of these methods the system can be more quickly impressed with the remedy.

Dr. Wilkinson has directed attention to the value of hypodermic injections of carbolic acid in carbuncle. Drs. Schuppert, Stewart, and Woodbury, in a series of valuable articles, have insisted upon the necessity of recognizing the difference between tetanus and tetany. The prognosis in the latter disease is almost always favorable while in the former recovery is rare. Tetanus is almost invariably a complication of a pre-existing wound or injury, while the so-called idiopathic tetanus is not true tetanus, but tetany. In tetanus the muscles of the jaws and trunk are primarily involved, in tetany they are not affected at all or only secondarily, the spasmodic contractions being usually limited to the muscles of the extremities. In tetanus the pain is agonizing, while in tetany it is comparatively slight.

The treatment of acute and chronic alcoholism by large doses of nux vomica or its alkaloid, strychnia, has been employed by many American and European practitioners with uniformly gratifying results.

The difficulty of making a diagnosis of gastric ulcer has been painfully illustrated in several cases, occurring recently in Philadelphia, in which the existence of this lesion was not suspected until actual perforation of the stomach took place followed by violent peritonitis and death. No blame can be attached to the attending physicians, for there were no symptoms indicative of the disease until medical aid was useless. It would be well, however, to bear these cases in mind when consulted for vague gastric symptoms,

and to test the effect of the dietetic and therapeutic treatment appropriate for ulceration of the stomach, if other measures do not give prompt relief.

The neurotic treatment of coryza has been enthusiastically advocated by Dr. Lees, of London. This treatment consists of the administration of belladonna and bromide of potassium and the local application of cocaine, and is admirably adapted to those cases which are produced by exposure to cold and dampness. The epidemic cases, however, which are assumed to be due to minute bacteria can be more effectually treated by the use of large doses of quinine, from three to ten grains three times daily. Dr. Davidson, of Georgia, has directed attention to the value of the hypodermic administration of nux vomica in the treatment of opium poisoning, and Dr. O'Daniels, of the same State, has obtained the most gratifying results from *phytolacca decandra* in the treatment of orchitis.

While no brilliant discovery like that of cocaine has been made in the field of therapeutic research since our last meeting, several valuable additions have been made to our armamentarium and our confidence in many older agents has been increased. Alveloz, a South American remedy for cancer, has been tested in a few cases with apparently good results. The pain has been mitigated, the discharge lessened, the fetor removed, and the ulcerative process checked. Dr. Smith Townsend has reported a case of lupus of the face of forty years' standing which had resisted all previous treatment but was cured by a few applications of alveloz.

Kairin and antipyrin have been found to be prompt antipyretics. Unfortunately the reduction of temperature which they produce is of brief duration and is frequently accompanied by the most alarming symptoms of depression. In one case fatal collapse ensued; the judicious practitioner will avoid their use for the present and rely upon aconite, quinine, salicylate of soda, oily inunctions, and cold affusions. The safest and most efficient antipyretic is cold water applied either in the form of cold baths, sponge baths, or the wet-pack. It must be remembered, however, that the fever does not constitute the whole disease, and that heroic antipyretic measures are not indicated when the temperature does not exceed 103° F.

A process, termed pneumatic differentiation, has been introduced as a panacea for all pulmonary affections, and a number of elaborate articles have been published in commendation of it in various medical journals. A company has been formed to manufacture pneumatic cabinets, and the announcement is made that the cabinets will be rented to reputable physicians for the modest sum of \$250 a year. The cabinet is practically an air-tight box in which the patient sits while a slightly greater quantity of air is forced into his lungs than he usually inspires. Some benefit naturally follows this increased admission of oxygen into the circulation, but greater benefit can be obtained by simply directing the patient to habitually breathe fully, slowly, and deeply while pursuing his ordinary avocation.

The peroxide of hydrogen, which is simply water impregnated with an excess of oxygen, has been found

to be a valuable antiseptic when used as an injection in leucorrhœa, gonorrhœa, cystitis and otorrhœa, and as a local application in diphtheria, foul ulcers, and fistulous tracts.

Antiseptic inhalations have long been used with benefit in whooping cough and bronchorrhœa as well as in phthisis. Among those which are now regarded as especially valuable are inhalations of creosote, turpentine, iodine, eucalyptus, benzoic acid, and carbolic acid.

Rhus aromatica, which was recommended years ago by Dr. N. S. Davis as a valuable remedy for incontinence of urine, is now coming into general use for that annoying complaint.

M. Caulet has directed attention to the value of the cold foot bath in insomnia and the various disorders dependent upon cerebral congestion.

Thallin, which was introduced as the ideal antipyretic, has been found to be more unreliable and dangerous than either antipyrin or kairin.

Syzygium jambolanum (jambol) has been recommended as a specific for diabetes. Clacius employed it in several cases, all of which exhibited marked improvement in a very short time, but further trial will be necessary to determine its value.

Jamaica dog-wood (*piscidia erythrina*) has been found to be a valuable sedative and hypnotic, and has the advantage of not being followed by constipation and nervous depression.

Hypnone and urethan also possess valuable hypnotic qualities, but their poisonous action upon the lower animals demands caution in their employment upon man.

Cascara sagrada has been ascertained to be an efficient tonic and laxative. It promotes the appetite, assists digestion, and overcomes constipation without producing any unpleasant effects whatever, and deserves to be admitted to the U. S. Pharmacopœia.

Dr. F. T. Paine has directed attention to the value of *salix nigra* in ovarian neuralgia, dysmenorrhœa, and all irritative conditions of the genito-urinary organs.

Dr. Tovar, of Cuba, has stated that parthenine, the active constituent of partheninum hystrophorus, possess marked value as an antipyretic and antiperiodic. The plant is used by the natives of Cuba as a substitute for quinine, to which it appears to be only slightly inferior. Its qualities deserve further investigation.

According to Korab and others, helenina, the active principle of *inula helenium* (elecampane) is a powerful antiseptic. A few drops of the solution of helenina immediately killed the organisms in ordinary infusions and proved fatal to the bacilli of tuberculosis.

It is recommended in cholera, cholera-infantum, malarial fever, and all the zymotic diseases, and may be substituted with advantage for carbolic acid in all preparations for external use.

Hyoscine has been thoroughly investigated by Dr. H. C. Wood and others, and found to be a potent sedative and hypnotic, and invaluable in the treatment of many disorders of the nervous system. As its action is prompt, and the susceptibility of individ-

uals varies, the initial dose should not exceed gr. $\frac{1}{8}$.

Hamamelis virginiana has been somewhat neglected by American therapeutists, but European physicians who have employed it believe it to be without a superior as an astringent and hæmostatic. It has been used with remarkable benefit in menorrhagia, hæmoptysis, hæmophilia, intestinal hæmorrhage, painful hæmorrhoids, purpura and varicose veins.

Nitro-glycerine has retained its position as the remedy *par excellence* for angina pectoris and chronic interstitial nephritis. It is also effective in the treatment of shock, opium poisoning, cardiac asthma, cerebral hæmorrhage and in failure of the heart's action during the administration of chloroform.

Strophanthus hispidus, a new remedy which has been introduced by Prof. T. R. Fraser, promises to take the first rank as a cardiac tonic and stimulant.

According to M. Germain Sée, Sparteine, the active principle of *spartium scoparium*, the ordinary broom-plant, is also a powerful cardiac tonic similar to digitalis and convallaria, but more prompt in its action and more durable in its effects. Broom has long been known to be a valuable tonic diuretic. Liebrich, to whom we are indebted for the discovery of chloral, has called attention to the value of lanolin as a basis for ointments. Lanolin is an animal fat derived from wool and other keratin bearing tissues. It is not a panacea. It will not answer to employ it in all cases of skin disease, but it is readily absorbed, and possesses many advantages over the materials ordinarily employed as the basis for ointments. Lewinin, a resinous extract obtained from the root of *piper methysticum*, has been ascertained to be a local anæsthetic of considerable value but not equal to cocaine. Hydrastis and its alkaloid, hydrastine, have been employed in dyspepsia, melancholia, neurasthenia, and various forms of skin diseases with beneficial results. Rothe has ascertained that *urtica dioica*, the stinging nettle, possesses valuable hæmostatic properties. Boldo has been tested by several distinguished French clinicians and found to be a valuable hypnotic and soporific. Pyridine, one of the constituents of tobacco smoke, has been introduced for the treatment of asthma, but does not seem to possess any advantages over the remedies usually employed.

Terebene, a derivative of oil of turpentine, has been investigated by Murrell and found to be especially valuable in the treatment of winter cough, bronchorrhœa, and other forms of sub-acute and chronic bronchitis. It appears to have a sedative as well as a stimulating effect upon the mucous membrane of the respiratory tract, allaying irritation and assisting expectoration.

Attention has been directed to the value of osmic acid administered hypodermically in obstinate cases of sciatica. *Sedum acre* has been employed in diphtheria with apparent benefit. *Ichthylol* has been found effective as a local application in chronic eczema and psoriasis, pruritus, and acute and chronic rheumatism. Its value is due to the large percentage of sulphur which it contains.

Euphorbia pilulifera has been recommended for asthma. Salicylic acid has been found useful in the treatment of diarrhœa. Large doses of sulphur have

been asserted to be curative in dysentery. Caffeine has been thoroughly studied, and is believed to be but little, if at all inferior to digitalis as a diuretic and cardiac stimulant. Its effects are less durable, but its action is more prompt and devoid of the dangers of digitalis. Renewed attention has been given to the subject of lavage in various gastric disorders and to the efficacy of oxalate of cerium in large doses as a gastric sedative. Arsenic has been found to be of especial value in the treatment of pernicious anæmia and other wasting diseases.

The subject of dietetics has attracted considerable attention during the past year and will receive far more in the future. Improper or unsuitable food is the most potent factor in the production and maintenance of many morbid conditions, and while temporary benefit can be obtained by the administration of medicines, no lasting cure can be effected until the exciting cause is removed. It does not require the gift of prophecy to foretell that in the near future dietetics and hygiene will be the watchwords of preventive medicine, and dietetics and therapeutics those of practical medicine.

It is impossible for me to close this address without deploring the loss which the American medical profession has sustained in the death of Dr. Austin Flint, Sr. Preëminent as a writer, teacher, and practitioner of medicine; acknowledged without a dissenting voice to be the greatest of American physicians, he bore his honors modestly, and never arrogantly asserted his superiority or used his great authority to the disadvantage of the humblest of his professional brethren. Kind of heart, studious of disposition, refined in conversation, gentle and magnanimous in character, faithful to the American Medical Association to the end, he passed away surrounded by love, honor, and scores of friends; but his work lives after him, and his spirit is with us still. For as Longfellow has beautifully said:

"Were a star quenched on high,
For ages would its light
Stream downward from the sky
Upon our mortal sight.

"So when a great man dies;
For years beyond our ken
The light he leaves behind him lies
Upon the paths of men."

ORIGINAL ARTICLES.

ELECTROLYSIS IN GYNECOLOGY; WITH A REPORT OF THREE CASES OF FIBROID TUMOR SUCCESSFULLY TREATED BY THE METHOD (WITH DISCUSSION).¹

BY FRANKLIN H. MARTIN, M.D.,
OF CHICAGO.

PROFESSOR OF GYNECOLOGY IN CHICAGO POLICLINIC; FELLOW OF THE CHICAGO GYNECOLOGICAL SOCIETY, ETC.

Electrolysis is the power of resolving compound

bodies into their constituent elements by passing through them a current of electricity. The constituent elements or *ions* of a body or *electrolyte* so divided, have a general tendency to arrange themselves around either pole of the battery—the *anions* going to the positive and the *cations* to the negative. Electrolysis only occurs in that part of the body which is in a fluid state. We know that if a galvanic current be passed through water, the element oxygen is attracted by the positive, and the hydrogen by the negative pole. The theory of electrolysis is: In every compound one of the elements (the one attracted by the positive pole) is electro-negative, the other the electro-positive. If a molecule next the positive electrode be decomposed, the electro-negative constituent of the molecule is attracted by that pole, thereby setting free the electro-positive constituent, which immediately grasps and combines with the electro-negative element of the next molecule, and so on, until every molecule has been similarly acted upon in the line of the current.

This is the theory. While this is true, we find that besides this simple "change of position," as Clausius calls it, we have a direct transference of fluid particles in the direction of the galvanic current. This phenomenon of direct transference was called by Du-Bois Reymond the cataphoric action of the constant current. This action can be demonstrated in a simple way by placing the electrodes of a galvanic battery in two compartments of a fluid, separated by a porous septum, when it will be seen that the fluid particles pass in the direction of the galvanic current, from the + to the — pole, and the fluid in one half of the dish will increase at the expense of the other half. It is by this action that dissolved substances are introduced through the skin by means of electricity.

Thus briefly and imperfectly I have stated the principle of electrolysis as it is observed in a fluid. When it is remembered that from one-half to two-thirds in bulk of all the soft tissues of the body is water, we can readily see how perfectly electrolysis can be accomplished in the various tissues. While the galvanic current passed through a soft living tissue has not an uninterrupted fluid medium, it has practically a fluid medium divided into innumerable little compartments, each one separated from the other by a thin wall of solid. During the passage of the current each of these particles of solids acts as a positive electrode on the fluid between it and the next solid particle in front, and as a negative electrode upon the fluid between it and the solid particle behind it. Each molecule of fluid in a conducting solid, therefore, in the line of a galvanic current becomes electrolyzed. It is found, also, in passing a galvanic current through a portion of the soft tissues of the body, that there is considerable tendency to a cataphoric action. That occurs by a direct transference of the fluid particles through the little permeable walls of solid in the direction of the negative pole of the battery. Thus we find the effect of electrolysis on a portion of soft fresh tissue to be: 1. A separation of the combined elements (more or less) into their constituent elements, and a rearrangement of

¹ Read in the Section of Obstetrics and Diseases of Women at the Thirty-Seventh Annual Meeting of the American Medical Association, May 5, 1886.

the same. 2. A general movement of elements in solution toward the negative pole of the battery.

Now, by a little ingenuity can we not readily explain how absorption is promoted by the process of electrolysis when applied to living normal tissue? A moderate galvanic current is passed through a part, and the most susceptible molecules in the course of the current become broken into their original elements: 1. These elements immediately make a similar or different combination with neighboring elements of opposite electrical tendencies, making thereby new-compounds which act as foreign particles; as foreign bodies they are promptly removed by the nearest absorbent. 2. Other elements, as they become free from their original molecules, make combinations with elements which are already leaving the tissues through one of their innumerable minute vascular or absorbent canals. 3. Many, in the form of gas, pour into the atmosphere beneath and surrounding the electrodes. 4. Others attack the electrodes and are disposed of in form of deposit on their surfaces. 5. The current by its cataphoric action, that is, by its direct transference of fluid particles in the direction of the negative pole, produces an engorgement of the tissues at the negative side of the part acted upon. The absorbents in that portion of the tissue will promptly make an effort to establish an equilibrium, and by a direct action of endosmosis they are filled and the excess is carried away in their current. This is what takes place in normal tissue, when the galvanic current is passed through it.

A similar change is produced in pathological tissues alone, or in pathological tissues incorporated with normal tissues. The ultimate effect, however, on the two tissues of repeated electrolysis is different, because of the constant effort upon the part of non-pathological or normal tissue to repair itself, and the inability, with a few exceptions, of pathological tissue to do so.

The successful use of electrolysis in medicine and surgery, then, must be based upon the fact that pathological material is not replaced after absorption is accomplished, as is normal tissue, unless its *cause* is still acting or is again brought into action. The practical application of these principles of electrolysis opens a large field for electro-therapeutics.

Therapeutical Applications.—With a rational knowledge of the simple principles given above, the air of mystery surrounding the beneficial results obtained from electrolysis immediately disappears. It is not necessary, however, to base our faith on theoretical grounds alone, because we have a substantial line of historical clinical evidence that perfectly accords with it. While it is not my purpose in this paper to give a complete *résumé* of electrolysis in surgery and medicine, I cannot refrain from mentioning a few of its most prominent advocates as additional proof of its efficacy. I am indebted to Dr. Robert Newman, of New York, for much valuable literature on this subject.

Historical.—Aneurisms were reported cured by Petraquin¹ as early as 1845. Since 1875 by Bow-

ditch,² Chauselle, Dujardin-Beaumetz, Laurent Robin,³ Sands, Sevir, Pepper, Keyes, Heath, Francesco Brancaccio⁴ and others.

Varicoceles have been reported cured by Dr. Robert Newman, of New York.

"Polypi, nævi, sebaceous tumors, and similar new formations, are promptly cured by electrolysis," says Bartholow. Nævi and port-wine marks are also reported cured by Beard;⁵ also by Hardaway, of St. Louis.

Subcutaneous erectile tumors have been treated with success by W. T. Hutchinson, of Providence.⁶

Ganglions have been cured by galvanopuncture by Dr. David Prince, of Jacksonville, Ill.

Epilation by electrolysis has been successfully accomplished by G. H. Fox,⁷ C. Heitzman and A. D. Rockwell,⁸ of New York.

Hydrocele has been reported cured by Althaus, Frank,⁹ Rodolfi,¹⁰ Erhardt¹¹ and Bartholow.¹²

Extra-uterine pregnancy has a record for electrolysis. E. G. Lander,¹³ T. Gaillard Thomas,¹⁴ Paul F. Mundé and A. D. Rockwell have succeeded in destroying the fœtus by the use of galvanism.

In bronchoceles of the cystic variety cures are reported by Amussat,¹⁵ Ultzman,¹⁶ Smith¹⁷ and Althaus.¹⁸ Of the solid variety cures have been reported by Wahltück,¹⁹ A. D. Rockwell,²⁰ and J. T. Everett.²¹ Morrell Mackenzie also reported nine cases cured out of thirteen bronchoceles with electrolysis.

Ovarian cysts have been reported cured by Van Ehrenstein, Clemens,²² Schmelder,²³ Vanderveer²⁴ and Mundé.²⁵

The radical cure of hernia by electrolysis has been accomplished by Dr. J. Craft, of Cleveland, O., and reported by Dr. Robert Newman, of New York.²⁶ After the hernia is reduced he causes a sealing-up of the inguinal canal by inserting a positive needle electrode, properly insulated except at the point, between the internal and external ring, and allowing a sufficient current to pass to excite adhesive inflammation.

Hæmorrhoids also have been cured by Dr. Craft by coagulating the contents by insertion of the positive needle electrode, or by absorption by inserting a negative needle electrode properly insulated except at point.

Epitheliomata have been cured by Robert New-

man,²⁷ A. D. Rockwell,²⁸ W. H. Massey²⁹ and Neftel.³⁰

Uterine fibroids have been successfully treated by Dr. Mesièrè, of Paris, who reported at the International Medical Congress at Copenhagen marvelous results in six cases by the use of electro-puncture. Dr. Apostoli, of Paris, reported at the same Congress the result of two years' treatment upon over 100 cases in which he had succeeded in reducing the size of the tumors and uteri, and completely restoring the patients. J. T. Everett,³¹ of Clyde, O., also reports successes in the treatment of these growths. Dr. J. N. Freeman,³² of Brooklyn, reported three successful cases by the method of electro-puncture. I am, myself, at present able to report the successful removal of two interstitial fibroids of well-marked dimensions, and the gradual diminution of a large subperitoneal fibroid which is still under observation. I will mention in detail these cases in another part of this paper.

Strictures in different parts of the body have done more toward developing electrolysis as a therapeutic measure than all other pathological conditions. Strictures of the nasal canal have been reported relieved. The lachrymal canal has been successfully dilated. M. J. Mercie³³ and M. Mercier³⁴ each report successful cures of dilation of the Eustachian tube by electrolysis.

Esophageal strictures yield to electrolysis. Professor Hjorth, of Christiania, reported an interesting case at the last International Medical Congress.³⁵ Frank, Butler and Prince also report successes. Female urethral strictures have been cured by Dr. Robert Newman.³⁶ Rectal strictures have also been cured by the same operator.³⁷ In regard to strictures of the male urethra, if all of the foregoing record fails to convince of the therapeutical and surgical value of electrolysis, the many valuable clinical reports of cure of stricture of the male urethra, by eminent men, can surely leave no doubt in the mind of the most incredulous.

Electrolysis was first used in strictures by Cusel, and subsequently by Millebrand and Werthemer.³⁸ The first recognized work of importance in urethral strictures was done by Mallez and Trepier.³⁹ Dr. Robert Newman,⁴⁰ the veteran of electrolytic treatment in America, and to whom we owe more than to any other *one* man for the successful development of this method, was at work as early as 1867, and reported results in the *Medical Record* as early as March of that year. From that time to this Dr. Newman has worked, and gradually improved his methods until he is now able to report over 100 cases of permanently cured strictures; that number having

been under observation long enough since treatment to warrant the statement "permanent cures." Besides the work of Dr. Newman, much successful work is represented by the reports of F. T. Frank, D. Prince, John Butler, Mynter, Benson, A. T. Douglas, G. C. H. Meier,⁴¹ W. H. Dukeman,⁴² J. H. Glass,⁴³ W. T. Belfield⁴⁴ and others. My experience in treatment of urethral strictures with electrolysis is limited to two successful cases.

Thus, briefly, I have given a summary of what has been done in many directions by the rational application of electrolysis. While the object of this paper deters me from going more fully into the details of the general subject, it presents much of great interest and value.

My experience with electrolysis, with the exception of the two cases already mentioned of stricture of the urethra, has been confined to gynecological practice. I have worked on the principles enlarged upon in the first part of this paper, viz.: 1. That a galvanic current of moderate quantity passed through a soft tissue of the body produces electrolytic action all along its course. 2. That a process of rapid absorption is produced in the parts so acted upon. 3. That the normal tissues, while the least susceptible to the current, and therefore least liable to be chemically decomposed, are, *if decomposed* and absorbed, almost immediately replaced by the inherent property of healthy tissue to repair itself. 4. That pathological tissue is usually of lower vitality than normal tissue, is more easily decomposed by the current, and when *it is decomposed* and its absorption accomplished it has not the power to reproduce itself.

The Battery.—The battery used for electrolysis must be one arranged for intensity rather than quantity. The Bunsen elements of zinc and carbon give the best satisfaction. The fluid should be weak, composed of diluted sulphuric acid and bichromate of potash. The current should be steady. Because of the small quantity of electricity generated by the small cells (great intensity only being necessary), the patient's limit of toleration can be reached without danger of a sponge electrode cauterizing if the battery be in proper order. Of the selection of electrodes I will speak, as the different indications arise, in detailing cases.

The pathological conditions which I wish to discuss, and in which I have received marked beneficial results, and not a few cures, will be included under the following headings:

1. Chronic Cellulitis and Peritonitis.
2. Chronic Ovaritis and Salpingitis.
3. Chronic Subinvolution of Uterus.
4. Chronic Hyperplasia Uteri.
5. Uterine Stenosis.
6. Laceration of Cervix Uteri.
7. Ovarian Cysts.
8. Peri-Uterine Hæmatocele.
9. Uterine Fibroids.

1. *Chronic Cellulitis and Peritonitis.*—Under this head I wish to consider all conditions in which in-

flammatory exudates have been deposited in the female pelvis anywhere, caused by a general or local peritonitis, perimetritis, parametritis, or inflammation of the cellular tissue surrounding the uterus and vagina, or in the broad ligaments. Under this head we meet with some of the most aggravating difficulties that the gynecologist is called upon to treat. Among the objective symptoms we find: Hardened, thickened condition of the anterior or posterior wall of the vagina; thickened deposits in Douglas's cul-de-sac limiting the movements of the cervix; thickened masses between the anterior portion of the cervix and the bladder, with adhesions; thick inflammatory masses latterly between the folds of the broad ligaments, displacing the uterus and interfering with its motion; and in many cases we have a general thickening on all sides with an immovable womb and tenderness in every direction. The subjective symptoms accompanying these various conditions are as varied as the objective. Besides the many local symptoms, we may have any or all of the organs of the body controlled by the sympathetic nervous system, involved in a sympathetic distress. The local symptoms include all forms of distress that may arise from interference with the functions of the pelvic organs. Constipation, sacralgia, dysuria, dysmenorrhœa, together with acute neuralgias in regions where twigs of nerves and sensitive nerve-ganglia are imprisoned in the inflammatory exudates.

While one or more of these multiform conditions are met with almost every day, we are almost helpless in our efforts to remove these inflammatory deposits and thickenings after they have become organized. True, we can promote absorption slowly, by the use of hot water, iodine, glycerine, massage, etc., and in cases of small deposits we may get absolute cures. It is in just these cases that electrolysis is indicated. Electrolysis, if properly managed, will promote the absorption of these exudates very rapidly, and in my hands has been the means of relieving a great many very severe symptoms together with their cause. I have a number of cases which properly come under this head, that I have treated with beneficial results, in not only relieving the symptoms for which I was consulted, but in which I also removed the inflammatory deposits. I will give the history of but one in detail, this one being a fair representative of the others.

Case 1.—K. D., aged 20; unmarried. Commenced menstruating at 14. Menstruation was painful from the beginning, and became gradually more painful as she grew older, until she consulted a physician. This was in her 18th year. While under treatment at this time she was taken suddenly ill with severe pain, and was obliged to remain in bed for some days. Before recovering from this acute attack she stopped treatment; was better of her menstrual difficulty, but was troubled with a great deal of soreness in the pelvis. This gradually left her. Her menstrual trouble gradually reappeared. Has had difficulty in passing water—frequent urinating with much pain. Has for some time been troubled in walking; has to bend forward when walking. Constipated; bowels have not moved for some time without medicine. Almost

constant backache. Cannot get rest in recumbent position. Almost constant "bearing down" pain night and day. Menstruation very painful, and pain continues all through the flow.

On local examination the external parts were found normal. Lower end of vagina large for a virgin; upper end contracted and hard. Cervix long and immovable at vaginal attachment. Pressure in vaginal vault gives cartilaginous feel with much tenderness. The whole upper part of the vagina is stiff, with uterus almost immovable. By bimanual manipulation the fundus is located in Douglas's cul-de-sac, and only slightly movable. Slight tenderness in ovarian region. Rectal examination shows considerable thickening of its anterior wall. Probe passed with difficulty into uterine canal, and took a backward course.

In this case there seemed to be a general adhesion of all the organs of the pelvis into one immovable mass. It was as though a liquid material had been poured on to the peritoneal surface of the pelvic organs, and after filling all the spaces between the organs had hardened. The patient was well nourished. She suffered excruciating pains while on her feet, and was far from being free from pain when lying down.

With the exception of the hot water vaginal douche, which the patient was using when she consulted me, I gave her no treatment except with the galvanic current. The treatment was applied in such a manner as to include as much of the inflammatory matter in the electric circuit as possible at each séance, and was varied so as to include all in the course of two applications. The external electrode was connected with the positive pole of the battery. This electrode is a flat sponge hand-electrode manufactured especially for me by the McIntosh Galvanic Battery Co., of Chicago (figure 1). It is a flat metal the length of the hand and about two and a half inches wide, covered on its inner surface with sponge, while the outer surface is covered with rubber, over which a wide band is fastened at either end, through which the hand is passed. This electrode is worn on the hand of the operator, and is narrow enough not to interfere with the flexion of the fingers. By means of this the operator can locate the uterus as in bimanual manipulation, and control the direction of the current perfectly. The negative electrodes used were of two forms, and were used on alternating days. One an ordinary rectal electrode of metal, insulated with hard rubber to within one inch and a half of the end, and about one-fourth of an inch in diameter, with an olive point (fig. 2 a); the other an ordinary vaginal electrode of metal, insulated to within an inch of the extremity, with the extremity round and about three-fourths of an inch in diameter (fig. 3 b). When the object is to promote absorption of pathological tissue some distance removed from the negative pole, it is well to have the metal covered with a moist piece of chamois.

The vaginal electrode was introduced into the vault of the vagina, and connected by means of flexible wires with the negative pole of the battery. The hand electrode was controlled by the right hand, as

the current was gradually increased a cell at a time by the left hand. The right hand with the sponge electrode, well moistened, is pressed firmly down over the uterus until the patient felt a smart, burning sensation of the skin. Then the vaginal electrode was pressed firmly into the vaginal vault and kept in one position throughout the *séance*. At different applications it was made to occupy different positions, but was not moved during a single sitting. In these positions the electrodes remained, and the current was allowed to act for ten minutes. Each alternate day the rectal electrode was used, the metal portion pressed firmly against the thickened anterior wall in such a manner as to cause the current to pass through the hardened exudate in the cul-de-sac of Douglas. Thus, in the course of a few sittings all portions of the pelvic cavity affected, helped to complete the circuit of the battery, and obtained the effect of the electrolytic action. This treatment was continued every other day, except through three menstrual periods, for about ninety days.

After a very few sittings the neuralgic pains commenced to disappear. At the end of three weeks there commenced considerable softening of the roof of the vagina. The anterior wall of the rectum became more pliable, and some movement of the uterus could be accomplished without pain. The sacralgia was less severe. At the end of about six weeks the fundus of the uterus could be moved forward with but little pain. The upper part of the vagina could be moved without difficulty, the walls having become soft and pliable. There is still some deposit in Douglas's cul-de-sac, and some immovability of the uterus at the vaginal insertion. The treatment was continued faithfully, although the patient considered herself about cured. At each *séance* the fundus of the uterus was forced forward by pressure on the anterior rectal wall with the internal electrode, and by forcing the fingers of the hand holding the external electrode behind it, it was crowded forward, and held in its normal position during the entire treatment. The patient improved rapidly; no pain at second menstruation. The inflammatory deposits rapidly disappeared, the uterus remained in its normal position as its adhesions became absorbed. At the end of three months the patient was perfectly well.

When I say perfectly well as far as I am able to judge, I mean *perfectly well* as far as *objective symptoms* as well as *subjective symptoms*, are concerned. This case is so remarkable that I consider it alone almost sufficient to establish the efficacy of electrolysis as a rapid, safe and painless absorbent.

The following case demonstrates the rapid absorptive power of the galvanic current on a large solid deposit:

Case 2.—Mrs. K. Age 28 years. Large, stout woman. One child two years old. Has painful menstruation. Pain in right side, aggravated by walking. Has been sick in bed a number of times since child was born, and at such times is always troubled with right side. The perineum is intact; cervix large and soft, and pointing to the left; uterus large, anteverted, with a left lateral tendency. Attempts to move the uterus increase the side pain.

The right broad ligament contains a large, well-defined, irregular mass of material, about 2½ inches in diameter, with a distinct cartilagenous feel. Manipulation produces excruciating pain.

This case was under treatment for eight weeks, and was completely relieved of all pain and all tenderness on pressure. The deposit in the right side was not entirely removed, but it was reduced fully three-fourths, and the uterus became perfectly movable. The treatment was advised continued, but patient left, well enough satisfied to be free from pain. The method was similar to that employed in last case, using the vaginal electrode alone internally. The treatment was used on an average of three times a week.

I might give the histories of other interesting cases of a similar nature, and with equally good results. These cases all vary in minor points, but the principles to be carried out are the same in all. Since commencing this article I have noticed in the *American Journal of Obstetrics* an article by Dr. Paul F. Mundé, on "Electricity as a Therapeutic Agent in Gynecology." He cites cases similar to the above, in which great relief was obtained and absorption promoted by use of the constant current. Was it not the electrolytic action of the current that produced the relief?

2. *Chronic Ovaritis and Salpingitis* are so intimately connected with all forms of pelvic inflammation that they may almost properly be considered under the head of chronic peritonitis and cellulitis of the pelvis. Ovaritis and salpingitis are so inseparable in their inflammatory diseases that in the late fashionable craze to unsex the woman they have both invariably disappeared together.

In a general pelvic peritonitis the ovaries and tubes seldom escape. They are intimately connected, and when the peritoneum is inflamed it bathes these intimately connected parts with the product of its inflammation, and from this the fibrous and muscular coats of the tubes, and the fibrous stroma of the ovaries, become involved. These inflammatory exudates, in process of hardening, contract, and limit the functional activity of these sensitive organs, and a general pelvic and ovarian neuralgia is the result.

In conditions of salpingitis and ovaritis, with inflammatory deposits, whatever the cause is, I am convinced great relief can be obtained, as far as the removal of deposits will give relief, by the judicious employment of electrolysis. I am certain that in a number of painful and serious conditions of this kind, I have obtained relief. At any rate, the method is well worth trying before advising the removal of the ovaries. True, there is very little relief to be obtained by any other non-surgical procedure.

The following case is a well-marked one of the kind, and one in which I think a cure was effected:

Case 3.—A young married woman, 26 years of age, with no children, consulted me for a pain in her side, which had been gradually increasing in severity for three years. The pain was constant, with excessive exacerbations for two days before each menstrual period, at which time there was also pain, though not so intense, on the right side. There was tenderness

on pressure in the left ovarian region, and if the pressure was persisted in it increased the pain so that it resembled that experienced before menstruation. In the left broad ligament a little body was discoverable which seemed like a prolapsed ovary. It was considerably enlarged and perfectly immovable. The right side was free from tenderness, and contained nothing abnormal. The pain of that side was evidently of a sympathetic nature.

For this patient electrolysis was recommended three times a week. The current that could be borne at the first few sittings was very weak—three or four milliampères being sufficient to cause increased pain in parts. The vaginal electrode (the negative) was crowded well up on the left side to the vaginal junction, and the external sponge-electrode passed gently over the region externally, so as to include the tender ovary and tube in the circuit. The patient soon became more tolerant of the current, and it was increased within two weeks to as many as fourteen milliampères. The patient got relief from the first application. The treatment was continued for about nine weeks. After the second week the continuous pain had entirely disappeared, although she suffered some at the first menstrual period. At seven weeks the pain and tenderness had disappeared; the menstruation was free from pain. Upon manipulation the ovary was found much reduced in size, movable, and free from all abnormal tenderness. Treatment was suspended after nine weeks.

The above case is only an example of what can be accomplished by this simple method. This woman had been blistered, morphined, and chloroformed, and had suffered in spite of all. She was in that desperate condition when I saw her, ready to submit to anything, even to having the ovary removed. That would have been the alternative if galvanism had not succeeded. The chronic exudate in the cellular tissue surrounding this ovary and tube was not only removed by the chemical action of the current, but undoubtedly the hypertrophied fibrous tissue entering into their intimate structure was reduced.

3. *Chronic Subinvolution.*—This condition is so frequently met with that I have had numerous opportunities of witnessing the beneficial action of galvanism in its treatment. I have noticed it gradually reduce in size while treating other pelvic conditions with galvanism where it was necessarily brought into the circuit. Paul F. Mundé reports cases of cure of subinvolution. He alternated with the galvanic current the faradic, also slow interruptions of the galvanic current. In such a proceeding the galvanism produced absorption of the excess of tissue, and the faradic, or the interruptions of the galvanic, caused contraction of the remaining muscular fibres. While faradization is more applicable in recent cases, shortly following confinement, before the muscular tissue has degenerated into a fibrous condition, in chronic cases the electrolytic power of the galvanic current is necessary. A. D. Rockwell also reports good effects from the galvanic current in subinvolution.

It is very seldom that an uncomplicated case of chronic subinvolution is found. There are usually other pathological conditions existing that have been

active factors in producing subinvolution. If the cause be constitutional of course it should have attention when the local treatment is applied. If it be local (lacerated perineum, lacerated cervix, subinvolution of vagina, etc.), before permanent cure can be established they also will have to be restored.

Case 4.—The following case is one of interest, although it alone would not be convincing evidence in favor of the electrolytic action of galvanism, because of other treatment being used in connection with it. A large well-nourished woman in good circumstances, aged 28 years, has one child six months of age. She has been slow in recovering from her confinement. She consulted me for general pelvic weakness, with "bearing-down pains," painful urination, sacralgia, constipation and excessive menstruation. Her menstruation had reappeared the second month after confinement. The perineum was badly lacerated, the vagina large, and the anterior and posterior walls prolapsed. The uterus was large, the cervix large but intact, with a patulous os. The uterine canal was large enough to admit the index finger to the first joint. The depth of the uterus was three inches. The fundus large and soft, normally located. This patient was given the benefit of a trial of general and local treatment, but with the assurance that I considered the restoration of the perineum would be necessary before a permanent result could be arrived at. She preferred not to submit to an operation until other means had been resorted to. I put her on ergotine and nux vomica internally. Hot water vaginal injections twice a day. Galvanism three times a week, followed by an application of a cotton tampon saturated with glycerine.

The patient improved in strength from the first. The pelvic distress was soon relieved, the backache stopped, and the difficulty in urinating gradually disappeared. The vagina contracted to about normal condition, the uterus rapidly returned to natural size, and the menstrual flow became normal. The uterus, at the end of eight weeks' treatment, with probe measured but two inches instead of three; the large spongy cervix was an inch in diameter instead of an inch and a half; and the large patulous os was closed and presented a natural appearance. The patient was so well after the eight weeks' treatment that she was quite inclined to reproach me for having so persistently recommended perineorrhaphy. The patient was under observation after treatment was discontinued for about eight months, when she became pregnant, and up to that time she had had no return of her former bad symptoms.

The internal electrode used here was a cervical electrode of metal, cup-shaped and insulated except the concavity of the cup (figure 4). This was introduced in such a manner as to have the cup support the cervix uteri. The circuit was closed by applying the hand sponge-electrode over the fundus. A current from ten to twelve milliampères was tolerated without pain, each séance lasting ten minutes.

4. *Hyperplasia of the Uterus.*—This condition, which in many respects resembles subinvolution, can properly be considered now. It does not necessarily, although usually, occur in women who have

borne children. It may be simply an inflammatory condition of the connective and fibrous tissue in a chronic subinvolved uterus, or it may be a general hyperplasia of the uterus, caused by the irritation of a lacerated perineum or cervix; or it may be caused from the irritation of repeated menstrual congestions which is made abnormal by a flexion or displacement of the uterus; or an error of nutrition from a general nervous derangement may be the exciting cause. *Whatever the causes are*, we find a large tender uterus, a thickened catarrhal condition of the endometrium, oftentimes an inflamed condition of the cervical glands, with the thick albuminous discharge welling out, and very often a well-marked abnormal displacement from the sheer weight of the organ. The condition is one of hypertrophy of the normal constituents of the organ from congestion and inflammation.

This condition will yield to electrolysis, although I cannot select any *one* well-marked case as an example. I have several times seen this condition yield to the chemical effect of the galvanic current when using it in other connections. In a condition often accompanying this I have seen very pronounced results, and it is worthy of mention because of the unsatisfactory results by the ordinary methods of treatment of the difficulty. I refer to *inflammation of the cervical glands*. This disease, with its characteristic tenacious albuminous discharge, every physician has had more or less to do with. The ordinary forms of treatment where cure is accomplished are harsh, and unsatisfactory in the extreme. Destruction of the deep gland tissue by curetting, cauterizing, or cutting, are the only methods that have heretofore given satisfactory results. These glands can be destroyed, or their condition of chronic inflammation reduced by the effect of repeated applications of a metal bulb of the negative pole of a galvanic battery. I first noticed this condition yield while treating other forms of pelvic trouble with electricity where it was desirable to pass a metal electrode into the cervical canal. One-half dozen thorough applications of this description, using a bulb electrode similar to those used for stricture of the urethra, and gradually increasing the size of the bulb, will, I think, cure the most obstinate cervical catarrh. A current of from fourteen to twenty milliampères can be used without producing any pain. I pass the bulb of the electrode through the internal os at each application.

5. *Strictures of the Uterine Canal* I have removed by electrolysis in a large number of cases. It was in this condition, at the suggestion of Prof. DeLaskie Miller, of Chicago, that I first used electrolysis. That gentleman had been using it with success for some time before my first attempt. It matters not what the condition is that produces the stenosis, or in what portion of the canal it exists. It has all the advantages over gradual dilation, divulsion or cutting, that electrolysis has in the treatment of male urethral strictures over gradual dilation, divulsion or cutting, viz.: painlessness, permanency, and, in case of gradual dilatation, promptness. There is little danger of producing a peritonitis by electrolysis.

The method of operating on these strictures is very

similar to that employed in strictures of the urethra. A small staff of soft metal, covered with hard rubber, upon the end of which one of a graduated set of olive-shaped metal bulbs may be screwed, is used for the uterine electrode. After making out the position of the uterus by manipulation, or by passing a small flexible metal probe, the staff of the electrode is made to conform with the supposed shape of the canal (figure 5). After this a flat sponge-electrode, attached to the positive plate of the battery, is applied to the thigh or abdomen of the patient, the internal electrode is passed into the cervix, either through a Sims speculum or a wide bivalve, and, while the cervix is steadied with a strong tenaculum with one hand, the electrode is guided by the other into the cervix until it finds its first obstruction, the current is gradually increased, while very gentle pressure is made on the electrode, until it passes in the course of the canal all the obstructions. Usually the smallest canal can be passed at the first sitting by a bulb the size of a No. 7 or 8 English catheter. This can be repeated with larger bulbs, if desirable, for three or four times, when it will be found that the canal is permanently enlarged.

(To be concluded.)

MEDICAL PROGRESS.

THERAPEUTICS OF TRICHINOSIS.—The value of glycerin in the treatment of trichinosis has been repeatedly alluded to. FIEDLER noticed several years ago, in the preparation of microscopic specimens, that trichinae and their embryos died at once when brought in contact with glycerin (even if diluted with two to three times its quantity of water). This was evidently the result of the hygroscopic power of glycerin, causing the abstraction of water from the parasites. This fact led Fiedler to treat animals, fed purposely with trichinous meat, with glycerine; but he did not obtain any positive results. Later he exhibited glycerin in several cases of trichinosis in man, and was successful. Mercel also published a case of trichinosis cured by glycerin, so that the profession regards this drug justly indicated in this affection.

In the *Deutsches Archiv für Klinische Medizin*, vol. xxxvii, No. 12, Fiedler recommends the hourly administration of a tablespoonful of pure glycerin in trichinosis, though only in graver cases, as large doses of the drug may produce hæmoglobinuria and other toxic symptoms.

In this instance the employment of Unna's keratine pills, or keratine capsules, which dissolve only in the small intestines, would appear very appropriate. To complete the abstraction of water from the parasites, Fiedler advises to give large doses of alcohol and to prescribe a rigid dry diet. Glycerin may also be injected into the rectum. A powerful purge, though, is to precede all these therapeutic measures. —*Therapeutic Gazette*, June 15, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, JULY 17, 1886.

"THE FUNCTION OF THE RECURRENT LARYNGEAL NERVE."

Such is the title of the admission thesis of Dr. FRANK DONALDSON, JR., of Baltimore, to the American Laryngeal Association, in May, 1886, which may be found in the *American Journal of the Medical Sciences*, for July, 1886. It is a question which has received but very little investigation heretofore, and Dr. Donaldson's discussion of it, with the conclusions drawn from experiments in the Physiological Laboratory of Johns Hopkins University, though short, must be considered as one of the most notable physiological achievements of the year, and a positive addition to laryngeal physiology.

How, and under what circumstances, does the constrictor or respiratory function of the recurrent laryngeal nerve assert itself? How are these functions to be differentiated? The nerve must contain two sets of fibres, innervating muscles of distinct and separate functions; whence do the two sets of distinct impulses come. Such are the questions asked by the writer. And as the filaments of this nerve have a distinct function, is the origin of these filaments as distinct as their functions? The known physiological facts concerning this nerve may be briefly stated as follows: It supplies both phonatory and respiratory muscles—it supplies all the intrinsic muscles of the larynx except the crico-thyroid—but it is chiefly a motor nerve; the internal thyro-arytenoids, the lateral crico-arytenoids, and the transverse arytenoid are adductor (phonatory) muscles of the larynx, and the posterior crico-arytenoids are the abductor (respiratory muscles) of the larynx; and as has just been said, all these muscles receive their nerve supply from the recurrent laryngeal nerve. And the main ques-

tion is, How is it that impulses travelling along this nerve alternately close and open the glottis? And how can we explain the fact that at one moment the nerve stimulus acts upon the adductors and at the next moment upon the abductors of the larynx.

Dr. Donaldson records nine experiments made upon dogs, the experiments being undertaken to test the following points: 1. Is it true that the constrictors cease to act during profound narcosis, or when consciousness is suspended from any cause? 2. Do we always get abduction of the arytenoids (dilatation of the glottis) on stimulation of the recurrent nerves, when consciousness is suspended? His interest in this subject had been awakened by the conclusions of Dr. F. H. Hooper, of Boston, "that stimulation of the recurrent laryngeal nerve always produced abduction of the arytenoid on that side, provided the animal was deeply under ether; that on removing the anæsthetic, the dilatation produced by stimulation became less and less as the animal regained consciousness, until finally contraction of the glottis followed; and that the abduction differed in different dogs. In other words, he concludes that the tendency of the glottis is to remain widely open, and that any given stimulus from the recurrent nerve would act upon the abductor muscles alone unless volition came into play, when the stimulus would produce the opposite effect and produce adduction." In the first five of Dr. Donaldson's experiments it was found that under no conditions was abduction of either or both cords obtained, except where the branch of the recurrent going to the posterior arytenoid itself was excited. In all cases adduction of the arytenoid was obtained, however deeply the animal was under the anæsthetic. In two cases it was found that when the animal was made thoroughly apnœic, and when for some seconds there was neither glottic nor respiratory movement, adduction was the result of stimulation; and in two cases, *after the animal was dead*, though of course before the death of the nerves or muscles of the larynx, stimulation caused closure of the glottis. "Under all these conditions of unconsciousness and narcotism, then, was *adduction* produced. This result followed, in these experiments, stimulation of the cut and uncut nerve; and followed chemical and mechanical, as well as electrical, stimulation." And in still another experiment, in which the branches of the recurrent to the individual muscles were dissected out and stimulated equally, none showed a tendency to a more rapid degeneration than another.

From these results it seems that the following conclusions are perfectly legitimate: 1. The constrictor muscles of the larynx do not cease to act during pro-

found narcosis or during suspension of consciousness from any cause; their action is independent of volition, in the sense that they lose their power during suspension of volition. 2. Abduction of the arytenoids does not always follow suspension of consciousness. Under what considerations, then, asks Dr. Donaldson, do we get abduction of the cords upon stimulation of the recurrent nerve? There must be some conditions, since abduction was obtained by Dr. Hooper, who thinks suspension of volition one condition under which stimulation of the recurrent caused abduction. Dr. Donaldson thinks that he has discovered the conditions under which the abductors act. He found that: 1. The abduction obtained by Hooper was in no way reflex. 2. Abduction is in no way dependent upon the unconsciousness of the animal. 3. It is with weak stimuli only that abduction of the cords takes place, which movement of abduction gradually passes into one of adduction as the strength of the stimulus is increased. 4. This result invariably followed, whether the animal was slightly, deeply, or thoroughly narcotized; whether the animal was eupnoëic or apnoëic, when the dog had his medulla destroyed, and after local death had taken place. 5. The rate of stimulation did not affect the general result. 6. After strong and constant stimulation the abductor muscles became worn out and ceased to respond to stimuli. 1. In apnoëa the cords came nearer the middle line, the abductors receiving no stimulus in this condition from the respiratory centre. "Here then, I think we have a suggestion as to the innervation of the muscles of the larynx." Dr. Donaldson agrees with Dr. Hooper that the assertion that the abductor fibres of the recurrent are prone to disease is unwarranted. "The clinical fact may be explained, however, by the theory of the greater irritability of the abductor muscle or nerve fibres. For in cases of unilateral lesion of the cords from an aneurism or tumor, the constant pressure exerted by either, acts as a mechanical stimulus to it, and the more irritable abductors are, therefore, the first to show the result of this constant stimulation, in their loss of function."

Dr. Donaldson would explain the innervation of the larynx somewhat as follows: Though the diaphragm and all the other muscles employed in respiration are voluntary muscles, breathing is really an involuntary act; and though we may modify respiration by the will, respiration habitually takes place without the intervention of the will. As the larynx is an essential part of the respiratory apparatus it must receive impulses from the respiratory centre in the medulla. It is necessary that the glottis be kept

open, and we find that the cords are pulled slightly away from their apparently normal position between extreme abduction and extreme adduction at each inspiration, even in normal breathing. "The fact that in deep narcosis the cords are pulled widely apart would seem to show that stronger stimuli than usual are proceeding from the respiratory centre to the abductor muscles; for in all deep narcosis the tendency is towards dyspnoëa, and always in this condition normal respiratory muscles are called into greater play. The constrictors of the larynx are apparently always in a state of partial tonic contraction, and ready for use at any moment. I found that in every case where the dog was thoroughly apnoëic that the cords came much closer together than in normal breathing; and this, it seems to me, is what we might expect, for in apnoëa the respiratory centre is at rest; and the respiratory function of the larynx being for the moment in abeyance, the protective or constrictor function of that organ asserts itself." He thinks, then, that both the respiratory and constrictor or (protective) functions of the glottis are governed by those laws which govern the rest of the respiratory apparatus. "There seems to be a similarity between the nerve fibres of the recurrent and those of the pneumogastric, and we are inclined to think that the great irritability mentioned above is in the nerve fibres supplying the abductors; the two sets of fibres of the recurrent supply opposite sets of muscles, and may be likened to the two sets of fibres composing the pneumogastric—the one answering to less, the other to stronger stimuli." Finally, he thinks that the constrictors of the larynx, which need a stronger stimulus to set them in action, may find that stronger stimulus in the numerous reflexes which arise on the introduction of a foreign body into the larynx.

EDUCATIONAL.

We are pleased to notice the frequent endowments given to the colleges and universities in this section of the country. During the last few years the Northwestern University has been particularly fortunate. Its fine location in Chicago's prettiest and most flourishing suburb, and its prudent financial policy, has attracted the attention of many wealthy men, and has led them to endow it liberally. During the last few years it has received two hundred thousand dollars, which has enabled it to clear off its old indebtedness and leaves it with a million and a half of property, much of which is rapidly increasing in productivity.

The latest gift, made within the past three months

by one who wishes to remain for the present unknown, is most timely. It consists of forty thousand dollars with which to erect a Science Hall for the accommodation of the departments of Physics and Chemistry. These departments have grown rapidly and their laboratory rooms have been cramped and uncomfortable. The walls of the new building are already well up. Its erection by the Northwestern University for these departments constitutes an epoch in the history of science at Chicago. It is the first building specially erected for instruction in these sciences in the city or its suburbs. The building is a double structure having a frontage of 130 feet, and a depth of 114 feet. The department of chemistry has its entrance in the left front, and occupies the left half of the building. The department of physics has its entrance in the right front and occupies the right half of the building. The structure is of two stories. The basement is built of stone, rock-faced. It is fourteen feet high and entirely above ground. On the outside, above the stone, is a water table of terracotta. Above this is the chief story, 16 feet high, the walls of which are of red brick. The whole height from the floor of the basement to the ridge of the roof is 56 feet.

The basement will be occupied by the heating apparatus and the steam power which will drive a dynamo and some machinery. For the department of chemistry it contains a laboratory for organic chemistry, a mineralogical laboratory, a store room, a general work room, a cloak room and a toilet room. For the department of physics the basement contains three special laboratories and two work rooms.

The main story contains in the department of chemistry a lecture room, a large general laboratory, a laboratory for quantitative analysis, a directors' room, a special apparatus room and a store room.

In the department of physics is a lecture room, a general laboratory, an apparatus room, a directors' room, a balance room, a dark room, a toilet room and a general work room. These laboratories have been planned by men who have worked in the best laboratories in this country and in Europe, and the plans have been submitted for the criticism of the prominent professors in other institutions in this country. It is believed that the result leaves little to be desired. The expense of the building is \$41,000.

The facts and the principles given to the student in lectures and in books will be verified by the student himself in these laboratories. The inductive sciences can be successfully studied only by experimental methods. The training of the mind in the inductive logic of the age, "the interpretation of

indications," *must be* in the laboratory—it cannot be by means of books. The College of Liberal Arts of this University, through its elective studies, gives to all students no matter what degree they seek, an opportunity to obtain this training. The new Science Hall, together with the recently established Biological Laboratory, places the scientific departments of this institution on a most excellent basis.

Its professional schools, consisting of the College of Medicine (the Chicago Medical College); the Union College of Law; and the College of Pharmacy, are located in Chicago, and are equally enjoying a good degree of prosperity. The practical laboratories of chemistry, histology and pathology belonging to the College of Medicine are among the best in this country. All these facts show that the Northwestern University with its several departments is an imposing institution, with a broad and stable foundation and a bright future.

EFFECT OF DRASTICS ON THE INTESTINES.

M. LUCIEN BUTTE three years ago concluded a series of experiments which were made in order to clear up the question as to the action of drastics on the intestinal mucous membrane of dogs. The experiments were made with colchicine, veratrine, croton oil and colocynth.

When colchicine was given hypodermatically or by the stomach it was found that it produced active inflammation of almost three-quarters of the small intestine, which showed a deep red color, with dark disseminated submucous hæmorrhages. About the middle of the duodenum were ulcerations as well defined as though cut out with a punch, the blanched color of which contrasted strongly with the red color of the mucous membrane. There were no traces of hyperæmia in the large intestine. These results, though in accord with the experiments of Roy, have been partly weakened by those of Pouchet, in a paper read by him before the Société de Médecine Légale de France, in February last. Pouchet made his experiments practically under the same conditions as Butte, found no hyperæmia or effusions of blood, and thinks that the ulcerations should be attributed to some other substance than colchicine.

As regards veratrine Butte confirmed the results of Vulpian, published in his "*Leçons sur les Substances Toxiques et Médicament euses.*" When veratrine is given either subcutaneously or by the stomach daily it has a very marked action upon the intestinal mucous membrane: the first half of the small intestine, especially the duodenum, is hyperæmic and has a rose color. The duodenal mucous membrane is the

seat of many oval ulcerations of a yellowish white tint, with a peripheral border and a central elevation. The large intestine is only slightly reddened. There are no large submucous ecchymoses; it is all limited to increased vascularity and slight effusions of blood. The inflammation is thus much less severe than in case of poisoning by colchicine.

On the small intestine croton oil has a very marked effect, but none on the large intestine. When given subcutaneously death results at a later period than when given by the stomach, and the intestinal epithelium, which is seen to be strongly colored by the biliary coloring matters, is so altered that small ulcerations are seen; showing that even when given subcutaneously croton oil has a selective action on the intestine, by which it appears to be eliminated. Death rapidly follows the injection of the oil into the stomach, preceded by vomiting and diarrhoea. The intestine is very violently irritated, much more so than by either colchicine or veratrine. More than half of the intestinal mucous membrane is of a uniform blackish red color, and there are extensive submucous ecchymoses. About the middle of the duodenum are seen a number of small superficial ulcerations.

The experiments made with the extract of colocynth were made in accord with those of Orfila. Singularly enough, this is the only one of the four drugs which produces changes in the mucous membrane of the large intestine; it causes alterations which are found almost throughout the whole extent of it. The most striking appearance is the presence of longitudinal red bands regularly placed along the whole length of the large intestine. On the small intestine the action of colocynth is much less intense. With this drug, as well as with veratrine, it is difficult to produce toxic symptoms when the drug is administered by the stomach.

Butte thinks that these experiments show that the drastics have a distinctive action upon the intestinal mucous membrane, which is peculiar to themselves, yet differing from one another in this action. While this may be true so far as is known, it scarcely seems proper to draw too definite conclusions as to what may be predicated in a medico-legal case involving these questions, since there may be other drugs which will produce analogous effects. The question may be an important one, however, and it is a field which might develop positive additions to our knowledge.

MEDICAL WRITERS AND TYPE-WRITERS.

While the type-writer cannot be included in any list of drugs, nor found in any catalogue of surgical

instruments, it must nevertheless be regarded as an adjuvant to good writing, and as a direct antagonist to bad temper, and should form a part of the armamentarium of "instruments of precision" of every one who does much professional writing. If each medical writer in the country—in the world—could spend one week in an editorial office and pass the time in reading manuscripts, the manufacturers of these instruments would acquire sudden and unprecedented wealth. Those who are in the habit of reading manuscripts know that writers vary, in regard to writing material, from the type-writer and new steel pen to the gold pen, the stylographic, the bad steel pen, the quill, the pencil, and (presumably) the walking-cane. It seems to be an immutable (and very unfortunate) law—whether psychological or not we need not stop to consider—that many who use quills, pencils and canes, and those who write illegibly generally, have in some way acquired a habit of discarding the accepted spelling of many words, and differ materially with certain good authorities on capitalization.

There are several reasons why medical men who write should use the type-writer. In the first place as a matter of economy of time, and hence, often, of money. It is easily seen that there is a great saving of time with a machine which will do a piece of work in one-half or one-third the time that it can be done by hand; and this is easily accomplished with a type-writer. In the second place, the machine promotes accuracy, especially in thinking, for two reasons: being more rapid than the pen, the thoughts of the writer do not wander so far ahead of his work; and should he wish to refer to what has been written he can see it at a glance, as on a printed page. A third reason is, the person who uses a type-writer sits erect, and can thus work for a longer time without fatigue than when bending over as in writing with a pen. It is thus more wholesome than the pen. The machine further promotes accuracy in the printing office—a great source of comfort to writers; and it promotes a degree of accuracy on the part of the writer in that he will not be able to make a wavy line or two or three letters and an apostrophe do duty for a long word, and his punctuation marks, if not more correct, will at least be less numerous. With a machine, therefore, writing becomes a pleasure, with none of the discomforts accidental and incidental to the use of the pen.

SURGEON-GENERAL ROBERT MURRAY, of the U. S. Army, will be 62 years of age in August of the present year, when he will be placed on the retired list.

Dr. Murray will soon have completed a long, efficient and most honorable term of service for his country. It is thought that Surgeon J. H. Baxter, who stands next on the roll, will be the worthy successor.

INTERNATIONAL MEDICAL CONGRESS INTERESTS ABROAD.—In Vienna, Austria, a local committee of twenty-five members has been formed for facilitating arrangements for attending the Ninth International Medical Congress in Washington, 1887.

It is stated in one of our exchanges that Professor James F. Harrison has resigned the chair of Practice of Medicine and Obstetrics in the University of Virginia, which he had held for several years past.

SOCIETY PROCEEDINGS.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 25th, 1886.

THE PRESIDENT, J. C. WILSON, M.D., IN THE CHAIR.

W. E. HUGHES, M.D., RECORDER.

DR. H. F. FORMAD read a paper on

INTRACRANIAL HÆMORRHAGE; RECORD AND CLASSIFICATION OF 143 CONSECUTIVE FATAL CASES OBSERVED IN MEDICO-LEGAL PRACTICE AND IN PRIVATE AUTOPSIES IN PHILADELPHIA.

There existed, he said, no well-defined descriptions of the various forms of intra-cranial hæmorrhage with reference to their etiology, and no classification that could be of any service in medico-legal examinations, and Dr. F. suggested the classification and observations presented below as particularly adaptable for the latter purpose. These records may also be of some use to the surgeon who wishes to trephine. The observations were sufficiently numerous to warrant conclusions of importance for various ends. He regretted that he met his cases on the autopsy table only, and hence was unable to offer clinical details. In some cases the history was far from being reliable, and in a few the history was left to conjecture from surroundings, the circumstances of the case, and the appearance and general lesions of the body. He wished to give credit to his colleague in coroner's work, Dr. R. R. Stewart, whose assistance in these observations he enjoyed, and also to his assistants, Drs. A. J. Plummer and George H. Chambers. Dr. Formad's cases of intra-cranial hæmorrhage embrace the results of various kinds of head injuries (traumatic), and cerebral apoplexies (idiopathic hæmorrhages) as well. By the term cerebral apoplexy he meant exclusively hæmorrhage in the brain, and did not refer to congestive, serous, embolic, or nervous apoplexies, and other affections which tyrannic nomenclature has thrown together under the name of apoplexy.

Idiopathic cerebral apoplexy should also be strictly separated from traumatic (this is *not* done by many writers). The latter can be further subdivided into very well defined sub-varieties of hæmorrhages, each etiologically distinct, as will be shown below. These observations will clearly show the necessity and usefulness of a classification such as suggested. There should never be any reasonable doubt at the post-mortem table as to whether a cerebral hæmorrhage was due to disease or to injury, or to both combined; nor as to whether a head injury preceded or followed an intra-cranial hæmorrhage. Dr. F. believed that the diagnosis between the conditions stated was much more difficult during life. He had seen errors made by foremost surgeons and physicians in the best hospitals in Philadelphia. Dr. Formad had seen cases of apoplexy diagnosed as fracture, and trephined, and he had seen cases of fracture of skull unrecognized and untouched, left to die in the medical wards.

Upon the post-mortem table, however, there should be no difficulty in diagnosing such lesions at the present status of morbid anatomy as a distinct and well-defined science. After sufficient accurate observations have been made and after seeing conditions to repeat themselves, case after case alike, and having in the majority of instances cause and effect directly before the eyes, one should be able, in disputed cases, to make a post-mortem diagnosis which leaves but little room for doubt.

Dr. Formad divided the cases of intra cranial hæmorrhage observed by himself into the following eight different classes.

Class I; 12 Cases. Post-mortem Appearance.

One or more small hæmorrhages in the fasciculi teres of the fourth ventricle; also, ecchymoses in the lining of the other ventricles (no massive hæmorrhage anywhere) cerebral substance as well as membranes intensely congested. Cranium much congested; drops of blood oozing from cut surface and from periosteum. Marks of contusion in scalp, with more or less ecchymoses, noted in all cases.

Histories.—In two cases death was caused by electricity (details will be recorded elsewhere). Ten cases revealed concussion of brain from injuries to head, without fracture of skull. Death was rapid or sudden from shock in all these cases. Six were males and six females; the majority were young persons.

Class II; 23 Cases. Post-mortem Appearance.

Massive hæmorrhage (blood-clot) of various sizes found between pia- and dura-mater, location in the majority of cases about opposite to place of application of violence. In none of these cases was the meningeal blood-clot located immediately beneath the point of application of violence. Ventricular ecchymoses also found usually. Brain anæmic in proportion to quantity of hæmorrhage. Scalp injury well marked in some, in others less so, while in a few cases it was hardly noticeable.

Histories.—Concussion from injuries to head without fracture in twenty-one cases; with fracture of skull in two cases. Death rapid (all within one hour) or sudden either from shock or from compression of

brain, the result of pressure from clot, or from both. Fourteen males, nine females; ages varied.

Class III; 45 Cases. Post-mortem Appearance.—Massive hæmorrhage (blood-clot) usually quite large, located between dura-mater and inner surface of fractured skull, and at the site of application of violence only. Brain anæmic.

Histories in all these cases revealed injuries to skull from accidents, blows or other violence, resulting in fracture of skull. Death on the average ensued slowly from compression or anæmia of brain in the lapse of from several hours to several days (in a few cases five to eight days). Thirty-eight males and seven females; majority young and middle-aged persons.

Class IV; 12 Cases. Post-mortem Appearance.—Massive hæmorrhage, the same as in the preceding class, but occurring both at site of application of violence and also at some point on apposite side of skull, the first, a large clot between dura-mater and scalp, while the latter in the arachnoid (between dura- and pia-mater), and usually small. At the site of injury there was found a fracture of the skull in all these cases, so that they presented the combined features of Classes II and III.

Histories in these twelve cases observed, showed injury to skull resulting into both fracture and concussion. Death was nearly instantaneous in all these cases. Nine were males and three females, mostly young and middle-aged persons.

Class V; 9 Cases. Post-mortem Appearance.—Punctiform and multiple hæmorrhages into the tissue of the dura-mater, which showed much thickening and adhesions to inner surface of skull from chronic hæmorrhagic pachymeningitis; great œdema of the pia-mater. Brain congested, but no blood-clots within cerebral substance.

Histories in these cases revealed former attacks of sunstroke or old injuries of head. Death usually sudden and usually following a fall or severe intoxication and excitement. Ages of deceased, between 20 and 50 years; all males.

Class VI; 34 Cases.—Massive hæmorrhages of various sizes into the brain-substance proper and thence into one or both of the lateral ventricles. Hæmorrhagic softening of brain-substance of corpora striata or their vicinity. No meningeal hæmorrhage in any of these cases, though in some blood was observed to have leaked out from the inner ventricles through the transverse fissure and fourth ventricle, and some usually liquid (post-mortem) blood would be seen in the cerebral fissures upon periphery in the meshes of the pia-mater and arachnoid. Brain-substance in nearly all cases quite anæmic. Atheroma of cerebral vessels in all but three cases. Multiple small aneurisms of cerebral vessels noted in several cases. Chronic pachymeningitis in various degrees in all but five cases. In some cases there were scalp injuries from secondary falls, *i.e.*, falls that were the result of preceding cerebral hæmorrhage. Many of these cases came under coroner's jurisdiction on account of suspicion of violence.

Histories, wherever obtainable, revealed either alcoholism, rheumatism, or syphilis; middle or advanced

age. Twenty-six males, eight females. Death in the majority of cases ensued slowly. These are true cases of idiopathic cerebral apoplexy.

Class VII; 6 Cases. Post-mortem Appearance.—Massive hæmorrhage of various size, below pia-mater, into brain-substance, without breaking into lateral ventricles. In one case the blood-clot involved the substance of the pons and protruded into fourth ventricle; in two cases it occupied the substances of the right parietal lobe, which was the seat of an abscess; in three cases the hæmorrhage was multiple, in small foci, with localized hæmorrhagic softening of periphery of brain-substance in various places. In three cases there was atheroma and in the other three fatty erosions of the cerebral vessels. Chronic pachymeningitis in all cases. Brain-substances congested.

Histories were those of former head injuries, alcoholism and probable syphilis. Death rapid, following intoxication, or exertion. Age advanced in all cases. Five men, one woman. Foul play had been suspected in all these cases.

Class VIII; 2 Cases. Post-mortem Appearance.—Massive meningeal hæmorrhage below pia-mater, combined with hæmorrhage into ventricles; no visible hæmorrhage into brain-substance. Atheroma and multiple; small aneurisms of vessels of pia and of choroid plexus. Echymoses in scalp.

Histories of accidental falls. No previous symptoms of cerebral disease had been noted. Intemperate habits; injury of the head leading to rupture of the diseased vessels evidently had preceded the cerebral hæmorrhage. The persons were at work (washing) at the time, when nearly simultaneous with the fall death ensued. Both were women; ages 57 and 63 years.

A number of cases of intra-cranial hæmorrhage observed by Dr. Formad he had excluded from the series above detailed. Several cases of compound comminuted fracture in which the skull, membranes and brain were partly pulpified into a mass and hence the hæmorrhage not being satisfactorily made out, were excluded from the above records. He also excluded chronic cases of cerebral hæmorrhage, and those resulting in abscesses or a fatal lepto-meningitis or cerebritis, after the patients had partly recovered from the immediate effects of the hæmorrhage. Dr. Formad did not incorporate into these records another large class of intra-cranial hæmorrhage, *viz.*: that of infantile meningeal hæmorrhage. Of these he had seen many in coroner's work. Meningeal hæmorrhage is common in infanticides and fœticides; and even in still-born children. Dr. Formad could not plausibly explain the frequency of meningeal hæmorrhage observed in still-born, otherwise than presuming that they were due to traumatic injuries from violence or to compression of the cranium during protracted labor, or when forceps had been injudiciously applied. He did not meet with cerebral hæmorrhage in children other than meningeal.

Returning to his classification, Dr. Formad stated that the quantity of the hæmorrhage or the size of the clot in any case of intra-cranial hæmorrhage appeared, in all the cases he observed, to depend upon the duration or the time that elapsed from the mo-

ment of injury to death. In cases where death ensued rapidly or instantaneously from shock, like in many fatal cases of concussion, or even in fractures of skull followed by immediate death, like in falls from a great height, the bulk of the ante-mortem hæmorrhage (the blood-clot) was remarkably small; or clots were occasionally entirely absent, and only a post-mortem oozing of liquid blood could be observed. When death is protracted for several hours, then the blood-clot was usually large, weighing up to six or eight ounces, and causing death by compression of the brain. In some cases of fracture of the skull the hæmorrhage is probably delayed for several hours, or ensues but very gradually. Some patients are said to have walked around for many hours after the injury, and subsequently, when the blood oozed out in sufficient quantity to compress the brain, they fell, became unconscious, and died in coma. In one case of this nature he had found a meningeal clot weighing eight ounces.

Dr. Formad observed that in the cases in which the intra-cranial hæmorrhage was voluminous and death instantaneous there was very little scalp ecchymoses; whereas scalp hæmorrhage was more pronounced if the intra-cranial hæmorrhage was small and death delayed.

Further, Dr. Formad noticed that in no case where there was internal cerebral hæmorrhage, was there any meningeal hæmorrhage when cerebral vessels were normal; and in no case of traumatic meningeal hæmorrhage did he see any coincident ventricular hæmorrhage (except small ecchymoses), unless there existed some old lesion of the vessels or substance of brain. It appears, however, that blood from the lateral ventricles may leak through the foramen of Monroe into the third ventricle and thence by the aqueduct of Sylvius find its way into the fourth ventricle, but Dr. Formad did not see in any one of the cases he observed that a primary hæmorrhage into the fourth ventricle ever extended to the lateral ventricles, probably on account of its rapidly fatal character. A hæmorrhage on the outside of an uninjured pia-mater cannot reach the interior of the brain or the lateral ventricles.

The source of the hæmorrhage is often very difficult to determine. In fracture of the skull, the hæmorrhage is often diploic; in concussion of the brain the hæmorrhage has for its source the vessels of the pia-mater: in diseased conditions of the brain or in atheroma of vessels the small feeding branches of the middle cerebral and of the basilar artery bleed most frequently, and the blood breaking into lateral ventricles forms clots in either one or both of the ventricles.

The views expressed by Dr. J. A. Lidell in his large "Treatise on Apoplexy" (New York, 1873, p. 133), that "meningeal hæmorrhage not unfrequently occurs spontaneously, as well as in consequence of the operation of violent causes," and that (see page 120) "meningeal hæmorrhage of spontaneous origin is not a rare affection," is unquestionably erroneous. Yet such "views" are quoted by writers on forensic medicine and presented to juries in murder trials as facts. Ignorant post-mortem examiners can set

murderers free, or on the other hand create unnecessary court-trials.

Dr. Formad's conclusions were:

1. Hæmorrhages exclusively above the pia-mater and above the dura-mater, *i.e.*, on the outside of the brain, are always due to *traumatism* or to *sunstroke*, provided a cerebral source for hæmorrhage is excluded and the cerebral vessels and membranes are not diseased.

2. Hæmorrhage in the floor of the fourth ventricle is always traumatic, provided there are no blood-clots in the lateral ventricles or any other part of the cerebral substance.

3. Hæmorrhage exclusively below the pia-mater, or in any part of the brain-substance or in the ventricles (except the fourth), is always idiopathic, *i. e.*, is due to disease.

4. A diseased condition of the cerebral vessels or substance is necessary in order to ascribe a hæmorrhage to disease; there must be traumatism (some form of violence or falls) in order to induce a hæmorrhage in a normal brain.

5. The blood-clot in concussion of the brain is not found at the point of application of violence, but always somewhere about the opposite side of the brain, and always within the arachnoid, *i. e.*, between pia- and dura-mater.

6. The blood-clot in fracture of skull is always found at the point of application of violence immediately below and always between the dura-mater and the fractured part of the skull itself.

7. A blood-clot formed within the cranial vault is more favorable to the patient if due to fractured skull than if due to a mere concussion.

8. Only clotted blood and infiltration of blood corpuscles into tissues indicates an ante-mortem hæmorrhage; liquid blood is due to post mortem oozing, and only stains, but does not infiltrate tissues.

9. Severe bruises and cuts of the scalp may be seen in cases of idiopathic apoplexy where a sudden cerebral hæmorrhage causes a person to fall.

10. In some cases it is impossible to decide by medical examination alone as to whether a head injury and the result is due to a fall or to violence.

11. External marks of violence may be invisible to the unaided eye in some cases of injury of the head or other parts, but are easily detected and also distinguished from post-mortem spots by means of the microscope.

12. The bulk of an intra-cranial hæmorrhage stands usually in inverse ratio to that of the external hæmorrhage into scalp.

DR. T. D. DUNN presented an unusual case of

CORTICAL HÆMORRHAGE WITH RHYTHMICAL CONTRACTIONS OF THE LEFT SIDE OF THE BODY.

A widow, æt. 73 years, came under his care June 23, 1886, with symptoms of congestive apoplexy. In a few days she recovered sufficiently to be able to leave her room. With the exception of some mental impairment for several months before the attack her health had been good. There was a second attack during the night. When Dr. D. saw her there were regularly recurring movements of the left side of the

body. Sensation and consciousness were not affected. The right side of the body could be moved at will, but articulation was impossible. The contents of bowels and bladder were discharged involuntarily. The movements continued during sleep. The movements gradually diminished, being lost in the leg on the fourth day and in the arm on the fifth. She died six days after the attack. At the autopsy a clot as large as a hen's egg was found situated on the right side of the brain, very superficially, extending from the ascending parietal convolution to the occipito-parietal fissure, and from the convolution of the longitudinal fissure to the temporo-sphenoidal lobe. The convolutions pressed upon and partially destroyed were the ascending parietal, the convolution of the longitudinal fissure, the supra-marginal, and the angular gyri.

DR. F. A. PACKARD presented a patient having a

CONGENITAL ANOMALY OF BOTH HANDS.

The right hand consists of a thumb, an index and a little finger, with only two metacarpal bones. The thumb has two phalanges and articulates with the same metacarpal bone as the index finger. The power of flexion is absent. The index finger has three phalanges. It can be flexed as a whole, but the individual phalanges are fixed. The little finger has three phalanges. The left hand consists of a thumb, index, ring, and little fingers, with four corresponding metacarpal bones. The patient is one of five children. His mother and father are normally formed; one sister has one hand that resembles his left; another has a left hand similar to his, and on the right hand has the middle and index fingers united throughout their entire length; one brother has both hands similar to this man's left. The only member of his generation not deformed is his twin brother. He has several children, all normally formed, and so, too, with his nephews and nieces.

DR. J. M. BARTON presented a

TUMOR OF THE STOMACH,

removed from the body of a man æt. 47 years. His digestion became impaired two years ago, and soon afterward he noticed the tumor. The symptoms were mainly those of chronic gastritis, with at one time a profuse hæmorrhage. The tumor was hard and well defined, and occupied the epigastric region. At the autopsy the tumor was found occupying the upper portion of the pyloric outlet of the stomach; did not encroach enough on the outlet to prevent the passage of a finger. It was found, on microscopic examination, to be a scirrhus carcinoma.

CHICAGO MEDICAL SOCIETY.

OFFICIAL REPORT.

Stated Meeting, June 21, 1886.

THE PRESIDENT, E. J. DOERING, M.D.,
IN THE CHAIR.

DR. FRANK E. WAXHAM read a paper entitled

INTUBATION OF THE LARYNX AS A SUBSTITUTE FOR TRACHEOTOMY, WITH A REPORT OF 83 CASES.

The author referred to the various modifications that had been made in the instruments within the past year. First, the enlargement of the heads of the tubes to prevent slipping into the trachea; second, the addition of a shoulder to prevent their expulsion; and third, a very important modification consisting of the construction of the tubes with thinner walls, giving greater breathing space and a better opportunity for the expulsion of false membrane. The author also presented a feeding bottle useful in those cases where they entirely refuse to take nourishment, as they will do occasionally, and also a trachea forceps for the purpose of removing false membrane by way of the mouth when there is detachment below the tube, or when it is pushed down ahead of the tube and cannot be expelled.

The author thought that the first question that would arise, in considering whether we had a substitute for tracheotomy in tubage of the larynx, would be as to the comparative success of the two methods. By personal inquiry and by correspondence he had collected reports of 306 cases of tracheotomy performed in Chicago with 58 recoveries, or a percentage of 18.95. The average in 138 cases was 5 years and 1 month.

In contrast to these statistics the author reported 83 cases of intubation with 23 recoveries, or a percentage of 27.71. The ages were as follows:

No. of Cases.	Age.	Recoveries.
1.....	9 months.....	0
1.....	11 months.....	0
1.....	13 months.....	0
3.....	14 months.....	1
1.....	15 months.....	0

2.....	8 years.....	1
1.....	11 years.....	0
7.....	0
83		23

Average age, 3 years and 7 months.

It will be observed that 11 cases with 3 recoveries were under 2 years of age; 28 with 8 recoveries under 3 years; 14 cases with 3 recoveries between 3 and 4 years; 15 cases with 6 recoveries between 4 and 5 years; 9 cases with 4 recoveries between 5 and 6 years, and 10 cases with 2 recoveries between 7 and 11 years.

Many of these cases were young nursing infants,

and many were delegated to him because they were too young or too unfavorable for tracheotomy. Of the 58 cases coming under his own personal observation, 20 were actually moribund when the operation was performed, many of them entirely unconscious, and 40 were bad diphtheritic cases characterized by severe constitutional symptoms and extensive diphtheritic exudation upon the pharyngeal walls. In only 18 cases was the exudation in the pharynx slight, but in every case, without exception, membrane was expelled either in the form of thick muco-pus, shreds or large casts. In every case the operation was performed to prevent impending suffocation, and the cases pronounced hopeless without surgical interference.

DR. D. A. K. STEELE, in opening the discussion, said that of course the principal interest to the surgeon centres in the question of the performance of tracheotomy in croup or diphtheria. I have looked up some of the older statistics, in addition to those given by Dr. Waxham. The French seem to have led the way in the practice of tracheotomy. Trousseau in 1858 gave the statistics as about 25 per cent. of recoveries, and from later reports tracheotomy does not seem to have gained much. Dr. Solis Cohen, of Philadelphia, in 1883 recorded some 5,000 cases, and his per cent. was the same as given twenty-five years before by Trousseau, about one in four. More recent statistics show some improvement in tracheotomy, for example, Dr. Jacobi, of New York, published 1,000 cases in which he had a little better success, if I remember correctly, than those reported by Solis Cohen. A few days ago I saw a report of seventy-seven cases from the Boston City Hospital, with a recovery of twenty cases, about 25 per cent. In Chicago the statistics, as given by Dr. Waxham, are 306 cases with a recovery of about 19 per cent.; these are the most recent statistics I have found. Of course, in regard to the report of cases of tracheotomy, we have to bear in mind a very practical point—that is, that the unfavorable cases are not all reported. The majority of physicians who do a few operations and have not a successful result do not record their cases. In New York City some twelve years ago a surgeon reported 67 cases with 13 recoveries. He made operations on 100 additional cases before he had another successful one; so there are curious mixtures and changes in the statistics of different operators.

Another point is that a good many surgeons report as successful cases that recover from the operation, but that die of some other affection or sequelæ, as this case reported by Dr. Waxham dying from albuminuria; all these cases are reported by tracheotomists as recoveries; but they are not recoveries from the diphtheritic croup. These points must be borne in mind. When we sum up, the statistics to-night would show a recovery of 27 per cent., which certainly seems to me to be a very favorable showing. In addition to these cases reported by Dr. Waxham, Dr. O'Dwyer has of late recorded 25 cases with a recovery of 24 per cent.; taking all those cases into consideration, the Chicago record is ahead of the New York record by 3 per cent. In regard to the Boston

City Hospital, where they had 25 per cent. of recoveries, we should bear in mind that those cases presumably have much better surroundings than we have in Chicago, or in general practice. There they have the best of nursing and immediate attention in case any mishap occurs, which in some cases in private practice might go unnoticed for many hours. With the favorable surroundings so far as the operation and the after-treatment are concerned, the reported recoveries of 25 per cent. are as favorable as we could expect.

Intubation is a comparatively new operation, but with the improved tubes (a serious defect in the construction of these tubes has been that the lumen was too small); I think that by enlarging the calibre of the tubes the percentage of recoveries would be increased. There would be less danger of rolling up the detached pieces of matter, and I think that expectoration would occur more freely. It is supposed to be necessary to have the tube extend down near to the bifurcation of the trachea, so as to prevent the curling pieces of membrane blocking up the opening, but I think they are longer than is necessary. The principal obstruction, we know, is at the larynx, the membrane below the trachea is thinner, smaller, and is not likely to curl up in this way. Theoretically the tube should be long, practically it might be shortened, and with the improved tubes we will get still better results.

A point in favor of intubation over tracheotomy is the rapidity with which it can be done, taking only the fraction of a minute to insert a tube in the hands of an experienced operator. We might also take into account the greater comfort of the doctor after the operation; the feeling of security with the laryngeal tube. I am constantly in dread after tracheotomy, watching and waiting, and seeing the little patients upon whom I have operated die one after another. Then the relief from dyspnoea seems to be quite as great after intubation as after tracheotomy. The relief from urgent symptoms is just as marked with the introduction of the laryngeal tube as with tracheotomy. In case we find intubation does not afford permanent relief it is no bar to tracheotomy subsequently, although where intubation does not relieve dyspnoea, tracheotomy will not relieve it; where stenosis is not relieved by the introduction of the tube, it does not relieve the dyspnoea.

DR. W. E. CASSELBERRY said his experience either with intubation or with tracheotomy has not been very extensive, but from it and from what he had gleaned from the literature of the subject, including the valuable paper presented to-night, he was very favorably impressed with the operation of intubation. The most favorable statistics of tracheotomy are those of not only the French, but more particularly of the large hospitals of France and Germany. In these institutions they have the fullest command of the patients in every way, the greatest attention can be paid them and the operation can be and is performed early. The most favorable statistics are those of Plenio (Konigsberg)—and of all the cases that were taken to the hospital but five escaped tracheotomy, showing that almost all were

subjected to the operation. The case of Dr. Ingals in which the membrane was removed from one of the bronchial tubes was a most brilliant one, but then intubation does not prevent tracheotomy from being performed afterwards. The forceps for the removal of the membrane through the mouth which the author has exhibited this evening is new; I have not much confidence in it, but perhaps it may be of value. In reference to the length of the tube, somebody has proposed that it should be shorter. I think it is the length of the tube which has rendered this operation successful over the operation of some eighteen or twenty years ago. It was invented by a French surgeon at that time, but the tube was only about $\frac{3}{4}$ of an inch long, sufficient only to reach into the larynx, where it excited irritation, and the operation was discarded as of no value; so that I think in the length of the tube we have an important feature. In reference to the introduction of the tube, if it is possible to practice on the cadaver it would be of great value; a minute is a long time when you are introducing a tube into the larynx of a child who is suffocating; you gag the mouth, introduce the forefinger as a guide to the larynx, follow it by the tube; the child stops entirely his feeble respiration, in a few seconds he becomes black in the face, and you are very anxious either to get the tube in or your finger out. If we bear in mind the instructions of the author of this paper to pass the tube under and not over the forefinger as a guide, I have no doubt we will be successful. And recollect that the curve into the trachea is a right-angled curve, so you must turn acutely and not obtusely or you will enter the œsophagus and not the trachea. The food of the patient is a most important point; when the tube is in liquids will frequently run into it and excite irritation.

DR. A. B. STRONG said: Before coming here I was prepared to endorse this operation to a great extent. I did not suppose the statistics were so favorable, but I am glad to find they are so. I have had quite a number of cases of intubation and of tracheotomy, and I must say I much prefer the introduction of the tube. However, not every case is adapted to the intubing; I think there are many cases where tracheotomy would be far preferable. We can feed a little patient after tracheotomy much better than after intubation of the larynx; to introduce a stomach tube would require the attendance of the physician several times a day. I have not yet given a fair trial to introducing the food into the rectum. I should not want a little patient that had suffered for three or four days before the operation to go without food; I like to feed my patients well, and certainly would not wish to starve them. There are three or four cases that have given me a good deal of information. The operation is new; we do not know all there is about it. One of the first cases that I had of true diphtheria, where intubing was done, was a little boy 4 years of age, taken sick five days before I saw him. The physician in attendance had given the child up, and I was called in. The little fellow was as near dead as any patient I had seen, but I would not have recommended tracheotomy in that case. The neck was badly swollen. Patient was cold, clammy, pulse-

less and cyanosed. Pupils widely dilated; apparently just on the verge of dissolution, mainly from profound blood-poisoning. I introduced the appropriate tube, and much to my surprise I nearly strangled him; indeed, for a moment I thought him dead. I drew the tube out and the child breathed a little bit better. It occurred to me that I might have crowded the membrane down. I introduced the tube again, with the same result; he was nearly strangled. I tried a smaller tube, but each time the tube went in the child nearly died. I laid him on the bed and surrounded him with dry heat. Brandy hypodermically. I did not suppose the child would live more than an hour, but to my surprise I received a telephone that he was alive and doing well ten hours afterward. I went to see him and found him with a good color, taking considerable nourishment. I called again in six hours just in time to see the child die. I had the privilege of post-mortem, and found exactly the condition of affairs I had anticipated. At the lower portion of the trachea I found a complete cast of that membrane crowded down. This case had been going on about five days when I saw it, and this membrane had been loosened in the meantime and so crowded down.

Another case was of a good deal of interest. A little girl eight years of age had a mild attack of diphtheria four days prior to my seeing her. Two days before I saw her the larynx first became involved, and gradually grew worse. The case was one of the most favorable for operation that I have seen. We introduced the largest sized tube and it remained in position for three days, and within 24 hours the lungs cleared up very nicely; at the end of three days and two hours the tube was removed with comparative ease, and I noticed that the child did not breathe as freely as I supposed she would. I remained about an hour, and during that time dyspnoea set in and the child nearly choked to death; we put in the one next in size and the symptoms were instantly relieved. The child wore that tube two days, when it died from bronchitis.

That case gave me this idea: the tube first introduced was as large as the parts would readily take in—it required a little force to introduce it—and it occurred to me that the tube was larger than was necessary. It remained there three days and two hours, squeezing the blood out from these parts, and when it was removed the sudden reaction caused the œdema of the larynx. The child wore that tube five days and a few hours, and until the last twelve hours of its life was getting along very nicely, except that it did not take the amount of nourishment I considered necessary. This operation is brilliant, and has a future before it, and I can heartily endorse it to-day. I am perfectly willing to try it, and I would prefer, in case of one of my own children, intubing the larynx to opening the windpipe.

DR. CHRISTIAN FENGER said: The subject is a most important one. As to the history of the operation, I would say that it is not a new one. A French surgeon, Loiseau, invented it in 1858, and to him belongs the idea. The instruments were, in the principle, about the same which we use now; there has

been modifications in details only. Tubeage was tried in France by Gros, but seems not to have found favor, although Bonehut recommended it without having used it himself. It was tried in Vienna by Weinlechner, who recommended it, condemned by Steiner and Ziemssen, and given up again. In reference to what was said about patients not swallowing at all for the first twenty-four hours, it seems to me it would be difficult to keep little children from drinking milk, or water perhaps, milk anyway, because they are always thirsty. There will thus be danger from foreign body—pneumonia (Schluck pneumonia). It might be that feeding bottles will obviate that danger. A second point is this: I saw a child treated by intubation die from loosened membranes closing the bifurcation. Whether the membranes were entirely loose or not, or loose above and attached below, is not materially important. The case convinced me that I would have felt safer with tracheotomy, because loosened membranes can be reached easier through the tracheotomy tube than through the larynx. As to the statistics, it is quite certain that the tracheotomy statistics are a little better than have been given here to-night. In the large hospitals in Germany the recoveries reach up, in the last few years, to 31 per cent. At the same time, when intubation shows 27 per cent., that is in itself reason enough for a trial. All these points are not exactly exclusively in favor of intubation, but like Dr. Strong, I should first try the tube, if it was my own child, and watch the patient incessantly, with the tracheotomy instruments on the table to be ready at any time when needed to resort to tracheotomy.

DR. S. STOCKTON was in favor of intubation.

DR. R. G. BOGUE said: There is much to recommend intubation I believe. The testimony we get is certainly enough to recommend the operation and to establish it as a practical procedure and one worthy of trial. It affords probably as much relief for the urgent symptoms, the one for which tracheotomy would be resorted to, as tracheotomy would; and the length of time that the tube is to be worn will be shorter than the tracheal tube. There are reasons why it should; from the pressure of the tube upon the membrane the presence would be likely to cause some disintegration of the membrane, and in that way the membrane would be taken away or gotten rid of sooner than without the pressure. The only objection—at least the one objection which occurs to me from what little I have seen, and what we hear, is the matter of fluids passing through the tube into the trachea and into the respiratory passages while attempting to feed the patient. That is an annoyance and probably a detriment. It also, I suppose, will deter children from trying to take fluids. Little children soon learn to avoid things which hurt them, and I should think that it would be a factor in preventing the free feeding of children. Now it may be that the introduction of fluid into the air passages may not be harmful, for as recently as to-day I saw in some report from New York the recommendation that in case of tracheotomy, where there is obstruction below the tube to pour fluid, by teaspoonful, for instance, into the tracheotomy tube, letting it run

down into the air passages for the object of liquefying and softening the membrane and getting rid of it in that way. That I think, is recommended by Dr. Geo. F. Shrady, who had practiced it recently with apparent benefit.

The question of introduction of fluid into the air passage may not be a tangible objection. But we would perhaps prefer to select the kind of fluid we would put into the trachea instead of milk or beef tea, or anything of that kind. The operation of tracheotomy has been resorted to for a great many years, with varying success by different operators and in different localities. Trousseau years ago, reported his success as about one in three, or three to four, from a very large number of cases. In the cases we have heard this evening as compared one with the other, tracheotomy hardly holds its own. The number of cases in tracheotomy no doubt are not all reported, but a fair proportion of them probably having been reported. While tracheotomy is certainly of great benefit, and has proved itself to be such in this class of diseases, it is subject to its disadvantages and annoyances; but so also has intubation its annoyances both to the patient, the friends and the doctor.

DR. C. T. PARKES: I have nothing but words of commendation as far as Dr. Waxham is concerned, for his persistence in presenting this method of O'Dwyer to the profession of this city. I have nothing to say about intubation; I have no experience, never having seen a tube used. I have had a little experience in tracheotomy, and so far as my personal experience goes, I shall stick to that until I have reason to change it. My experience extends over thirty-one cases of tracheotomy. I had the honor to report to this society on previous occasions the first fifteen cases; eight recovered and seven died. I have collected the names and residence of sixteen more, and of these ten have recovered and six died. That is a pretty fair showing. I cannot explain, do not pretend to explain this percentage of recoveries. You will find in the literature of tracheotomy throughout the world that some operators have a good fortune in that respect. I do not think it an unusual or peculiar fact that the doctor relates about relief given to the patient when you open the trachea after stenosis; cases in which the patients are unconscious, black in the face, and are revived by the introduction of the laryngeal tube, such a result is to be expected. I see by the report very few if any of these cases recover after intubation; I know I have seen just such cases recover after tracheotomy. I have never had any trouble from the swallowing of fluids or food of any kind; I have seen the fluids come out of the opening of the tube, and have had the physician in charge reporting that we had unfortunately made an opening into the cesophagus; those cases have never given trouble, and in a few days subsided. There is one peculiarity about these cases of intubation, that Dr. Bogue has explained, the pressure of the tube causing an early disappearance of the membrane. There have been no cases that I have seen in tracheotomy, where the tube could be removed under six days; in two cases it was three or four months before the tube was removed; I have never seen the trachea

opened so far, without seeing false membrane come out of the trachea. If I were enabled to remove the tracheotomy tube inside of six days or a week, I should think that to be a case in which no membrane was found in the trachea and one, in all probability, if I had waited a few days, in which the patient would have gotten well without any operation. There is something peculiar and interesting in the ages of these sixteen cases, the youngest being $3\frac{1}{2}$, the oldest 37 years of age. I think the cases in which stenosis has been complete, and required an opening of the trachea, have been very few in the adult. One of these operations was upon a woman after she had been sick some four or five days with a bad case of pharyngeal diphtheria. At the time I saw her she was absolutely suffocating, and I was called for the purpose of performing tracheotomy; I did the operation under very poor surroundings and yet the patient recovered. The tracheal opening became diphtheritic. Another case was 32 years old. The patient died on the table; this accident has happened in quite a number of cases. I never had any trouble with the children and certainly expected less with the adults, as in the latter the operation is much more simple than in the child. This patient stopped breathing before the trachea was reached, and after it was opened it was impossible to restore respiration. As far as I am concerned, I can say nothing about intubation, I think it is very likely I shall purchase a tube. I don't know whether or not it is such an easy thing to intube the larynx; I think I have cognizance of three cases not in the doctor's list that proved fatal, in which some difficulty was met. One 3 years old died the day after. One 7, in which no relief was given, as the membrane seemed to be pushed ahead of the tubes, and one in which no relief being given, the attempts to remove was complicated by the child swallowing it and being buried with the tube in its stomach. Another, a young lady 17 years old. This patient recovered; she was relieved immediately after the introduction of the tube, and rested very comfortably until the next day when she complained of a pain in her stomach. In the evening of that day she passed the tube from the rectum. I allow you to judge of the necessities requiring its use, so I don't know that I can agree with these gentlemen and say the operation is simple. We know what tracheotomy amounts to, and I am sure I would not feel right about it, I should be haunted with the idea of not doing my whole duty, if I left a child 7 years old go without doing tracheotomy where I felt satisfied, after this tube was introduced there was no relief given. I think tracheotomy will always have a place. I have been asked so many times how I come to have this record of tracheotomy, that I think it is due me to say one thing more; I do not know how to explain it. I believe no other operation for tracheotomy should be done but the high operation. The trachea should be opened at the highest ring, and if necessary, divide part of the cricoid, as I have done, or all of it. Certainly the after care has a great deal to do with the recovery, and I do not believe there are any persons so wanting in intelligence, but if you give them instructions carefully they will carry them out. So far

as my experience goes, the surroundings have made no difference, even if it be a house of only one room with the whole family living in it, and several other animals besides. I think the room should be kept at a temperature above 80; there should be no attempt to fill it with moisture, the room should be so hot as to be decidedly uncomfortable for all the friends, for the first twenty-four hours. During this time (twenty-four hours), the inner tube of the trachea should be removed every hour whether the patient seems to need it or not, because that is the time when the deep seated trouble in the organs below starts. After that time I do not believe the tube should be removed oftener than seems absolutely necessary, and I do not believe that mucus can be prevented from drying by the introduction of foreign bodies. Every time the tube is removed it should be reintroduced damp, or wet in a mild solution of soda, and occasionally without taking out the inner tube, drop into the trachea a few drops of this same fluid so as to keep the end of the tube as moist as possible. No foreign bodies of any kind should be introduced into the trachea after you are quite certain all the pieces of membrane had been detached and removed at the time of the operation. The introduction of such an innocent little thing as a feather or sponge I am satisfied does more harm than good. I am willing to admit that in one case which showed every sign of recovery, the tube was moist and the cough was moist, and I had every reason to believe it would get well, but owing to over anxiety I kept poking feathers into the trachea and had the friends do the same, until I got up an inflammation of the trachea proper around the tube, which I am satisfied was the cause of the fatal issue. I do not think there should be any interference; the least possible interference is the best plan of cure.

DR. H. T. BYFORD said: I wish to call attention to one fact; that is, in the statistics of hospitals tracheotomy shows about as favorably as intubation, although in private cases the safety, simplicity, and absence of formidableness of intubation makes it already the popular operation. As I have said before this, tracheotomy is an operation for hospital practice, where the difficulties can be overcome, and where its just claims for precedence in particular cases must always obtain consideration.

DR. F. E. WAXHAM, in closing the discussion, said: I believe every tracheotomist will entertain an opinion in regard to tracheotomy according to the success which he has attained. If a physician has saved every patient upon whom he has operated, he will feel that the operation is good enough, and will be perfectly satisfied; if he has saved a large proportion of his cases he will be loth to accept anything new; but the great majority of physicians, who have either met with unvarying failure or inferior success, will have a poor opinion of the operation. English writers seem to be losing faith in tracheotomy, for Holmes, in his "System of Surgery," says: "English medical men seem very generally to incline to the opinion that the operation, if not to be recommended, is at least justifiable, but to be successful it must be performed at a very early period of the

attack." Referring to Professor Parke's remarkable record of tracheotomy, I can not help feeling that his cases could not have been so unfavorable. I cannot believe that he had many young infants to operate upon. I would like to ask the age of his youngest patient?

DR. PARKES: Three and a half years.

DR. WAXHAM: That explains why his record has been far more successful than that of many physicians. I believe that if tracheotomy were performed upon every case without reference to age, condition, or type of disease, we would not save more than one out of every ten or twelve. Many physicians select their cases; indeed, I know of some who *will not* operate upon a child under three years, and of others who will not operate upon diphtheritic cases on account of the known fatality occurring after tracheotomy in these cases.

In regard to the difficulty of performing intubation, I would say, that any of you who attempt the operation upon a child without practice upon the cadaver, will certainly be sorry for it. I have known of four physicians who have failed completely. In regard to the patient to whom the last speaker referred, the young lady with the tube in her stomach, that case I am afraid was not in my record. I, unfortunately, or perhaps fortunately, did not secure the patient.

Dr. Parkes has stated that after tracheotomy, if he were able to remove the tube in less than six days he would have concluded that there could have been no membrane within the larynx, and that if he had waited a few days longer the patients would have recovered without the operation! May I be pardoned for feeling that the natural inference would be, that in these cases of intubation because the tube has frequently been removed on the third, fourth or sixth day, that there could have been no membrane present and that the operation was unnecessary? In reply, I would state that in every case coming under my observation false membrane has been expelled when the tube was introduced. The reason why the laryngeal tube can be removed earlier than the tracheotomy tube is, that more or less membrane is detached when the tube is first introduced, and second, the pressure of the tube and the frequent coughing assists in dislodging the membrane; while after tracheotomy little or no air passes through the larynx until after the removal of the tube, and there is nothing to cause the dislodgement of the membrane.

In regard to feeding the patient: Many of my patients have taken abundance of nourishment without difficulty. Occasionally, however, there will be one that will not take a sufficient amount. It will depend a great deal upon the size of the tube. If we use a tube larger than is appropriate for the age of the patient, it will not always fit perfectly into the cavity of the larynx, and consequently the epiglottis will not close accurately over it. In a case such as Dr. Strong has referred to, where the membrane is pushed down ahead of the tube, the trachea forceps would be very useful in removing it.

There are a great many dangers from tracheotomy that are never met with from intubation; but we rarely hear of them. I have learned of one physi-

cian who attempted a tracheotomy on a child four years old. Cutting down hastily he severed large blood-vessels, and losing his head at the sight of the copious hæmorrhage, at once sewed up the wound, while the child, almost with his last breath, wanted to know if they were going to cut him any more. Another physician, in cutting down hastily in order to open the trachea, missed it, and accidentally severed the carotid artery. Indeed, the history of tracheotomy is replete with horrors, but we do not hear of them. In the hands of experienced surgeons, who are cool and collected, the operation may be a simple and safe one; but in the hands of the inexperienced and the nervous, performed, as it frequently is, in the dead of night, it then becomes a formidable, yes, a dangerous procedure. Intubation, on the other hand, can be performed quickly, in a very few seconds, and without the dangers attendant upon tracheotomy.

NINTH INTERNATIONAL MEDICAL CONGRESS,
TO BE HELD IN WASHINGTON, D. C.,
COMMENCING SEPT. 5, 1887.

PRELIMINARY ORGANIZATION.

SECTION XIV. PUBLIC AND INTERNATIONAL
HYGIENE.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—I have the honor to submit the following with reference to questions N and O, relative to *Quarantine*, proposed for discussion by the Fourteenth Section of the Ninth International Medical Congress:

The idea which I had in propounding questions N and O, was for the purpose of bringing about a grand union of action on the part of all civilized nations on the subject of *Quarantine*, so as to advance the cause of medical science and humanity.

As matters now stand commerce is made to bear the *brunt* of *Quarantine*. The unfortunate ship stricken by pestilence suffers detention and in some cases immense expense. The unfortunate crew and passengers, who have committed no crime, are treated like *outcasts* and *outlaws*. They are supposed to have no rights which humanity is bound to respect.

Commerce bears in its bosom the germs of civilization; commerce establishes and sustains the markets of the world; commerce is the agent for the dissemination of all that is grand and noble in the life and development of our common humanity; and the brave and hardy sons of commerce have in all ages and in all times rallied to the defense of their native lands.

Is it just, is it right, that the pestilence-stricken ship should bear all her expenses, and suffer all that the safety of man may demand and that avarice and cowardice may suggest?

Has not civilization advanced to that stage, and are not the great civilized and Christian Powers of the world (the United States of America, the British Empire, France, Germany, Austria, Russia, Italy, Spain, Portugal, Denmark, Norway and Sweden) sufficiently strong, wealthy and enlightened to estab-

lish a uniform system of quarantine which should embrace:

1. A system of mutual confidence; a uniform system of registration of diseases and deaths.

2. A system of regular health reports, giving detailed statements, weekly, monthly and annually, and if necessary daily, of all matters relating to the public health—to the sanitary welfare of nations. By the use of the telegraph all civilized nations could be kept informed of the appearance, spread or arrest of any contagious or infectious disease, as small-pox, cholera, yellow fever, etc.

3. A uniform system of quarantine, adapted, of course, to the climate, latitude, and endemic or epidemic diseases.

By a *uniform system* we mean uniformity in the construction of quarantines, and their administration, and the uniform assumption by the great Governments of the world of all quarantine expenses of cleaning, fumigation, and the treatment of the sick. The only expense necessarily borne by the pestilence stricken ship, or by the *suspected* ship, detained in quarantine, would be the loss of time and the necessary expenses for food of crew and passengers.

As quarantine is now conducted, the owners of ships as well as the passengers and crews suffer, often unequally and unjustly, for the general good.

The two questions are complementary one to the other; and to make this relation plain we re-state them.

N. Shall the General Governments of the civilized world assume control of all the quarantine systems, and by mutual consent reduce the entire subject of quarantine to order, and apply the most improved methods of sanitation and disinfection?

O. Shall the Government of the United States assume charge of the entire subject of quarantine (within her own borders), and relieve the individual States of all further responsibility for not merely foreign, but also inter-State quarantine?

O flows necessarily from N; to be of any practical value the discussion of N must precede that of O; O cannot be construed as relating to anything but the United States of America and its individual States, and does not refer to foreign States, only so far as one of the contracting parties under proposition N.

I hope that the high purpose by which I am actuated in propounding these questions is clear—the discussion is for all civilized nations, and the earnest hope is entertained that great good will grow out of it for the protection of commerce, the advancement of medical science and the welfare of humanity.

Your obedient servant,

JOSEPH JONES, M.D.,

President Section XIV, Public and International Health, Hygiene, Provisional Organization Ninth International Congress.

156 Washington Ave., New Orleans, La., July 7, 1886.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th,

9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

DR. A. M. POLLOCK, of Pittsburgh, Pa., has been appointed Secretary of the Section of Surgery and Anatomy of the American Medical Association for the present year.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

(Concluded from page 55.)

An Excursion to the Catskills—The Ulster County Medical Society—Mr. Henry Berghon Pasteurization.

But to return to our medical excursion party. The ride in the cars up through Stony Clove was a most picturesque and charming one, and it was rendered all the more attractive by the masses of wild laurel in full bloom all along upon the mountain sides. The finest part of the Clove is that near its upper entrance. Here the depth between the two great mountains—Hunter on the one side and Spruceback on the other—is extremely narrow, and the rocky and precipitous cliffs, covered with stunted evergreens, tower to a vast height on either side of the road. Those on the Hunter side, particularly, form an almost perpendicular wall, and present an aspect of wild and indescribable grandeur. It is here that the ice-cans, where ice remains throughout the entire year, are found; and in summer the temperature is always considerably lower at this point than in the surrounding region. After leaving the Clove, the scenery is not less beautiful, and the romantic terminus of the railroad, on the shore of one of the two lovely Catskill Mountain lakes, seems a fitting place of ending for so inspiring a ride. Stages are in waiting for the party, and by six o'clock all are safely landed at the hospitable doors of the great Hotel Kaatskill, whose

"arces

Alpibus impositas tremendis,"

white and gleaming in the sunshine, we had long been watching from afar.

With keen appetites we sat down to a bountiful supper, and afterwards wandered off to enjoy the declining day.

— Sol ubi montium

Mutaret umbras . . . amicum
Tempus argens, abeunte curru.

At half-past eight the scientific session was resumed, and Dr. H. Van Hoevenberg read a paper of medico-

historical interest in regard to the City of Kingston. The Provincial Congress, which was obliged to leave New York on account of the arrival of the British army, assembled at the court-house in Kingston March 6, 1776, and immediately proceeded to organize a form of government for the State. The first constitution of the State of New York was probably adopted here on April 20, and two days later it was read aloud to the people by Robert Berrian, Secretary of the Convention, standing on a barrel in front of the court-house.

The most important business before the Convention having been finished, the trial of a number of Tories was taken up, and two of them were hung. Up to a year ago a large oak tree, standing just on the verge of the town, was known as the "Tory's oak," and was said to be the tree on which a number of Tories were hung during the Revolution.

On July 11 an election was held, and George Clinton was chosen Governor. Among the persons present at the inauguration of Governor Clinton was Dr. Luke Kiersted, who at that time was a very prominent man in the community.

The result of the action of the Convention at Kingston, and the proclamation of Clinton as Governor, was that the British sent a force of about 1,600 troops, under General Vaugh, who landed at the mouth of the Rondout Creek, and marched up to Kingston, where they immediately proceeded to plunder and burn the houses and barns of the inhabitants. Most of the able-bodied men of the place were with the Continental army in the Highlands, and although a detachment was sent north to protect Kingston, it did not arrive until the work of destruction was nearly completed.

The Ulster County Medical Society was organized in Kingston July 1, 1806, with Dr. James Oliver as President, and Dr. Luke Kiersted Vice-President. In looking over the records of the Society it is found that even in those days the profession was troubled with quacks, and one of the first things that it did was to take action concerning a number of illegal practitioners. At the annual meeting in 1807 it was voted to choose some subject for debate at the succeeding one, and that the President should appoint some one to open the discussion. Accordingly "Fever" was the subject selected, and Dr. Samuel H. Phillips was appointed for the purpose. It is found that as Dr. Phillips did not appear at two subsequent meetings, he was fined \$5; and the speaker thought that this might perhaps be a good precedent to follow at the present day under similar circumstances.

Dr. Van Hoesenberg said, in conclusion, that there were inscribed on the roll of the Society the names of some who have been men of marked ability, men who, with the opportunities which would have been afforded them in one of the large cities, would have risen to high position in the ranks of the profession. But they were content to live the life of usefulness that opened before them, doing all the good that they could to those around them, often at the cost of hardships and sacrifices; many times getting little, if any, pay, and sometimes more curses than thanks as their reward.

The opponents of Pasteur are not likely to have their cause materially advanced in the eyes of the general profession by the following expression of opinion by Mr. Henry Bergh, which was given in connection with some comments on the recent experiments on dogs by Dr. Spitzka, made for the purpose of showing that so-called cases of hydrophobia could be produced at will by the introduction of various foreign substances into the brain after trephining: "Pasteur is in the way of doing great harm to mankind. He has never proved that he treated a case of pure hydrophobia. He has never cured a case of hydrophobia. Yet, by creating a scare, he has worked upon the public mind so that people intelligent in most things have been convinced that he has made a great discovery. His discovery has a parallel in Jenner's, who has done more harm to the world than any other man. What can be more senseless and illogical than to put into the blood of a child the discharge from a diseased animal? It doesn't prevent disease, but spreads it. A great number of the cases of cancer, scrofula and consumption have appeared as a consequence of this method of treatment, by which poisonous matter thrown off by one body is infused into another. Such diseases have not spread among savages or among people not subjected to this treatment, and I am amazed that persons of intelligence should submit to it." 'The Quixotic President of the Society for the Prevention of Cruelty to Animals seems to be totally unaware that he is paying the highest possible tribute to the preventive treatment of Pasteur by coupling his name with that of the immortal Jenner.

BOOK REVIEWS.

A TEXT-BOOK OF MEDICAL PHYSICS. FOR the Use of Students and Practitioners of Medicine. By JOHN C. DRAPER, M.D., LL.D., Professor of Chemistry and Physics in the Medical Department of the University of New York, etc. With 377 Illustrations. 8vo., pp. xxxii, 733. Philadelphia: Lea Brothers & Co. 1885. Chicago: A. C. McClurg & Co.

We cannot too earnestly hope that this, the first work on medical physics in this country, is the forerunner of a new era in medical education. Thus far our colleges may, with but few exceptions, be said to have "thrown physics to the dogs." As a demand will create a supply, so it is to be hoped that in this case a supply will create a demand for a good textbook on medical physics.

Those who have studied Ganot and Deschanelle will note the conspicuous absence of mathematical formulæ and problems in reading Dr. Draper's work; even the familiar one which is supposed to prove that an air-pump cannot be completely exhausted is omitted; and mathematical formulæ are even omitted from the chapters on light. And in this connection it may be said that one of the best chapters in the book is that on the microscope, which treats well of dry objectives, immersion objectives, of the prepara-

tion of slides and covers, of objects, of hardening and section-cutting, injection, staining, chemical testing, and of everything else pertaining to the use of the microscope. The book may be regarded as a most excellent addition to truly medical literature.

NECROLOGY.

DR. SIMON STRAUSSER.

DR. SIMON STRAUSSER, of Chicago, Ill., died at his residence in that city, April 22, 1886. He was born in Enebach, Bavaria, in 1833. He received an academic education in his native country, and where he began the study of medicine at the Polytechnic Academy of Wurtemberg, though he did not finish his course. In 1848 he emigrated to America, and a year later attended lectures at the Jefferson Medical College, serving at the same time as an interne in one of the hospitals. While so engaged he made the acquaintance of a student from Virginia who invited him to visit his family at Alexandria. This invitation was accepted, and while there he made many friends who assisted and encouraged him, and he began the practice of medicine without having received a degree. In 1854 he was married to Miss Clara Tupper, and in 1857 removed to Philadelphia where he practiced until 1867, when he removed to Chicago, Ill. He there acquired a supporting practice and became a member of the Chicago Medical Society in 1879, receiving in the same year the degree of M.D. from the Rush Medical College. He was a laborious student, a conscientious and careful practitioner and devoted to his profession. Dr. Strausser lost his first wife in 1862, and in 1869 was married to Miss Pauline Schlaus, of Pittsburgh, Pa., who with three children, survive him. For the past year the doctor was conscious of failing health, but kept attending to his duties as best he could, and worked up to ten o'clock of the night on which he died. His death was sudden, and caused by angina pectoris. He was a member of the American Medical Association, attending the meeting in 1883 at Cleveland. Resolutions of respect to his memory were adopted by the Chicago Medical Society, May 3, 1886. J. M. T.

MISCELLANEOUS.

HEALTH OF MICHIGAN.—For the month of June, 1886, compared with the preceding month, the reports indicate that intermittent fever increased in prevalence. There was no marked increase or decrease of any other disease. The temperature was higher, the absolute humidity considerably more, the relative humidity and the day ozone were about the same, and the night ozone was more.

Compared with the average for the month of June in the eight years. 1877-1886, remittent fever, measles, intermittent fever, pneumonia, bronchitis and diphtheria were less prevalent in June, 1886. The temperature was slightly lower, the absolute and the relative humidity were about the same, the day ozone was more and the night ozone was considerably more.

Including reports by regular observers and others diphtheria was reported present in Michigan in the month of June, 1886, at forty-seven places, scarlet fever at forty-eight places, typhoid fever at six places, measles at sixteen places, and small-pox at three places.

Reports from all sources show diphtheria reported at four places less, scarlet fever at nine places more, typhoid fever at the same number of places, measles at five places less, and small-pox at three places more than in the preceding month.

OFFICERS OF STATE SOCIETIES:—The Ohio State Medical Society at its 41st annual session at Akron, June 2, 3, 4, 1886, elected the following officers: President, Thomas MacEbright, of Akron; First Vice-President, J. M. Weaver of Dayton; Second Vice-President, W. S. Battles, of Shreve; Third Vice-President, X. C. Scott, of Cleveland; Fourth Vice-President, Jesse Snodgrass, of Kenton; Secretary, G. A. Collamore, of Toledo; Assistant Secretary E. C. Bush, Zanesville; Treasurer, T. W. Jones of Columbus. The next meeting will be held in Toledo.

The Kentucky State Medical Society at its 31st annual meeting held at Winchester, June 23, 24, 25, 1886, elected the following officers: President, W. H. Wathen, of Louisville; Senior Vice-President, J. M. Harwood, of Shelbyville; Junior Vice-President, J. H. McKinley, of Winchester; Permanent Secretary, J. Steel Bailey, of Stanford; Assistant Secretary, T. C. Simpson, of Bardstown; Treasurer, Edward Alcorn, of Hustonville; Chairman Committee of Arrangements, J. G. Brooks, of Paducah. Next place of meeting, Paducah the third Wednesday, in June, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 26, 1886, TO JULY 2, 1886.

Col. Thos. A. McParlin, Surgeon, granted leave of absence for two months, with permission to apply for an extension of one month. (S. O. 146, A. G. O., June 25, 1886.)
Lt.-Col. Chas. Page, Surgeon, leave of absence extended ten days. (S. O. 146, A. G. O., June 25, 1886.)
Lt.-Col. D. L. Magruder, Surgeon, granted leave of absence for two months, to take effect on or about July 1, 1886. (S. O. 146, A. G. O., June 23, 1886.)

PROMOTIONS.

Lt. Col. Jos. B. Brown, Surgeon, to be Surgeon with the rank of Colonel, Jan. 24, 1886.
Major Anthony Heger, Surgeon, to be Surgeon with the rank of Lieut.-Colonel, Jan. 25, 1886. (Circular A. G. O., June 25, 1886.)
Major Richard S. Vickery, Surgeon, assigned to duty as Surgeon in charge of Army and Navy General Hospital at Hot Springs, Ark. (S. O. 150, A. G. O., June 30, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JULY 3, 1886.

Green, E. H., P. A. Surgeon, ordered to Naval Laboratory at Brooklyn, temporary duty.
Brown, J. M., Medical Director, member of Retiring and Examining Board.
Ogden, F. N., Asst. Surgeon, ordered to "Juniata."
Siegfried, C. A. Surgeon, three months' leave abroad.
Hall, J. H. H., P. A. Surgeon, detached from Museum of Hygiene, and ordered to Naval Hospital at Brooklyn.
Wentworth, A. R., Asst. Surgeon, detached from "St. Louis" and ordered to "Brooklyn."
Decker, Corbin J., Asst. Surgeon, ordered to "St. Louis."
Berryhill, T. O., Asst. Surgeon, ordered to Museum of Hygiene.

ELECTROLYSIS IN GYNECOLOGY; WITH A REPORT OF THREE CASES OF FIBROID TUMOR SUCCESSFULLY TREATED BY THE METHOD (WITH DISCUSSION).¹

BY FRANKLIN H. MARTIN, M.D.,
OF CHICAGO.

PROFESSOR OF GYNECOLOGY IN CHICAGO POLICLINIC; FELLOW OF THE
CHICAGO GYNECOLOGICAL SOCIETY, ETC.

(Concluded from page 68.)

6. *Laceration of the Cervix Uteri.*—This is a condition which of course cannot be repaired by electrolysis. I hope I will not be considered as riding a hobby, however, if I assert that temporary relief can be obtained from the results of laceration of the cervix by the proper use of electrolysis. The painful consequences following this condition of laceration are due in great part to formation of cicatricial tissue in the fissure, to degeneration of the mucous follicles, to obstructed circulation in the neck, and to connective tissue changes, and a congestive hypertrophy.

By experience in just this condition, when the privilege of trachelorrhaphy was withheld, or when for some other good reason I was deterred from operating, I have obtained very gratifying *temporary* results. I emphasize *temporary*, because time enough has not passed since the operation to warrant me in saying permanent. However, because of the nature of the condition I do not expect to get permanent relief in these cases, although in two typical cases I have seen complete relief which has lasted four and six months respectively.

Case 6.—The first of these was that of a primipara who had been confined in the country two years before she consulted me. The laceration was a deep bilateral fissure, with hypertrophied, angry, congested appearing lips, with a large quantity of bloody albuminous discharge hanging from their surfaces. The patient presented all the subjective symptoms usually accompanying such a condition, including general anæmia and nervous irritability, with menorrhagia. The treatment, besides good feeding, was hot water vaginal injections, and a thorough application of galvanism directly to the cervix. The cervical cup was used for the internal electrode, with an occasional application to the canal with the bulb electrodes. The patient improved rapidly from the first. The

hypertrophy rapidly subsided, the hypersecretion was checked immediately, and in five weeks the patient was discharged. At this time, as she was in the best possible condition for a trachelorrhaphy, I rather insisted upon the operation, but she preferred to "run her chances," inasmuch as she was, to all personal feelings, well.

Case 7.—The other uncomplicated case is one that came from a prominent specialist, and had been treated in preparation, I judged, for a trachelorrhaphy, although the operation had not been suggested to the patient. She had been under treatment for three months, receiving local applications from two to three times a week. She had improved but little after the first month. The cervix had a deep bilateral laceration, the left extending to the vaginal junction. The cicatricial plug was almost like cartilage, and a general hyperplastic condition of the whole cervix existed. The case was treated exclusively, with the exception of small doses of arsenic, by electrolysis. At the end of two months the cervix was soft and pliable, the two lips easily coming together, much reduced in size, and the congested condition had disappeared. The patient considered herself cured, although I cautioned her that the symptoms might return.

This method of treatment is so prompt in relieving this condition that it is destined to become very popular as a temporary measure, or as a general measure when there are insurmountable barriers to an operation. As a preparatory measure for trachelorrhaphy it surely possesses very superior claims.

8. *Ovarian Cysts.*—I have had no experience with electrolysis in this condition. And with the present successful standing of ovariectomy, I think it will gain very little popularity in that direction. Dr. Paul F. Mundé² said recently in writing on the subject: "Many of us may still remember the claims of Dr. Frederick Semeleder, of Mexico, some eight years ago, that ovarian cysts were curable by electrolysis, and may also recall his experiments with the method here, and his disastrous results." Dr. Mundé still further says: "I made it my object at that time to collect all the cases in literature of electrolysis for ovarian tumors, and to compile the cures and failures, and published a full article on the subject in the *Gynecological Transactions* for 1877, vol. ii. I collected fifty-one cases, of which only twenty-eight might credibly be considered cured; nine died, and fourteen were utter failures. The ratio of mortality and failure was 45 per cent., or double the mortality

¹ Read in the Section of Obstetrics and Diseases of Women at the Thirty-Seventh Annual Meeting of the American Medical Association, May 5, 1886.

² American Journal of Obstetrics, December, 1885.

from ovariectomy, even in the hands of our less successful operators of to-day." He adds, "That settled the question of electrolysis."

While Dr. Mundé's statistics do not show very well for electrolysis, we must remember before giving it an unqualified condemnation that electrolysis as a surgical procedure in ovarian tumors is in its infancy compared to abdominal section in the same condition; and we must also remember that his statistics exhibited but nine deaths in fifty-one cases, or a mortality of less than 18 per cent. Of course failure to cure the other fourteen by electrolysis did not preclude the last alternative, ovariectomy. I do not believe that the first fifty-one cases of ovariectomy performed exhibited anywhere near as good a record as Dr. Mundé's statistics show for electrolysis. Let us wait, therefore, for further developments before passing too severe judgment.

9. *Peri-Uterine Hamatocoele*.—Dr. Apostoli* recently described a method of treating this condition by means of negative-galvano-puncture as follows: "The chemical caustic action of the continuous current is utilized in making an opening into the tumors. The opening thus made is, in character, a non-retractile fistula, with tendency to remain open, and with adhesions between the pathological cavity and the external mucous membrane. . . . The advantages of this method are that, on account of the adhesions formed, the danger of opening is lessened, and the cicatrix left by the negative eschar is slight and non-contractile. A further after-effect of this method of utilizing the chemical caustic action of this current is that the nutrition of these pathological cavities is modified, leading to retrograde metamorphosis."

Apostoli has treated one case by this method, and the excellent results obtained lead him to the following general conclusions: "The method is safe, quick in action, and modifies the usual prognosis. The method is, in action, double—it has a surgical effect and a medical effect." He adds: "It is applicable alike to hæmatocoele, abscess, fibromata, interstitial myomata and extra-uterine cysts."

10. *Fibroid Tumors of the Uterus*.—Fibroid tumors have been reported cured by a process of electrolysis by a number of operators.* The popular method heretofore adopted has been the electro-puncture. This is accomplished by means of needles made of steel, silver or gold, of different lengths according to the requirements of the case to be operated upon (figure 6). These needles are insulated to within a short distance of the point. They are made so that they may be connected with either pole of the battery by means of flexible wires.

Method of electro-puncture: If a subperitoneal fibroid tumor is to be operated upon, a point is found, if possible, where a needle from one or both poles of the battery can be introduced into its substance without wounding the peritoneum. This often can be accomplished by passing the needle through the

substance of the uterine walls, and entering the tumor at its attachment to the uterus. Sometimes the needle only from one pole of the battery is used, while the circuit is completed by applying the electrode from the other pole, which should be a very large flat sponge electrode (figure 7), upon the surface of the body in close proximity. If two needles are introduced, one from each pole, they should not come in contact at any point. Sometimes in large abdominal tumors the needles are thrust through the abdominal walls into the substance of the growth. In any of these procedures it is usually necessary to administer an anæsthetic. The strength of the current must depend upon the manner of application, and what is to be accomplished. If both poles are connected with needles, and the needles are buried in large tumors, a greater strength of current can be used than when one electrode is on the skin. The current is usually increased in strength one cell at a time until the negative needle is well loosened by the chemical decomposition of the current. The séance should last from ten to fifteen minutes, and be repeated in ten days if necessary. Three or four applications well carried out are sufficient usually to decidedly reduce large fibroids. The above method is substantially the one adopted by Dr. J. N. Freeman, of Brooklyn, and Dr. Menière, of Paris.

Another method adopted and described by Apostoli, which is only applicable for interstitial and sub-mucous fibroids, is a mixed treatment of the faradic and the galvanic currents. His manner of application of the current is such that the current will pass through the largest part of the tumor. The needles are not used. His idea is to get the effect of the two currents—the chemical effect of the galvanic, and the contractile effect of the faradic."

The treatment which I have adopted is the same as that already described for removal of inflammatory exudates, the reduction of the hyperplastic uterus, the absorption of cicatricial tissue, etc. A current of high tension and small quantity is used. A current of this quality is applied as strong as the patient will bear. The negative electrode is applied in the vagina, the uterus, or the rectum, while the positive pole is applied on the skin in a position that will cause the current to pass through the largest diameter of the growth. The internal electrode is metal, and may or may not be covered with chamois. The séance should last from ten to twenty minutes, according to the susceptibility of the patient and the strength of the current. While this method may not be as applicable for very large tumors as electro-puncture, on small interstitial growths its action is very prompt and satisfactory.

My experience in this treatment is confined to three cases of fibroid tumors. The cases are so typical and the histories so complete, and the effect of treatment so prompt, that I shall look for much good to come from the treatment of fibroids by this method.

Case 8 is that of a young married lady, aged 25,

* Quotation from American Journal of Obstetrics, April, 1886.

* Association Française pour l'Avancement de Science.

* See another portion of this paper for authority.

* Dr. Apostoli has of late adopted the strong galvanic current in the treatment of fibroids.

who had been married five years. I was first called to her because of acute neuralgia of the heart. At this time I learned that she had been troubled with excessive menstruation for nearly two years. She afterwards consulted me at my office. She complained of the excessive menstrual drain, excessive backache, pressure on bladder, and hæmorrhoids. She was anæmic and very irritable. Upon examination I found the cervix low in the pelvis, the uterus apparently large, with a patulous canal. Further examination showed what seemed like a large fundus in Douglas's cul-de-sac. By making a combined rectal and abdominal examination I was immediately convinced that I had a large growth in the posterior wall of the uterus to deal with. Upon passing a sound into the uterine canal with a finger in the rectum, I was able to estimate the growth to be about two and a half inches in anterior posterior diameter, and occupying a portion of the enlarged uterine wall about three inches in diameter. It bulged on the peritoneal surface about one and a half inches. It was hard and firm, and on rectal and abdominal examination seemed to be about the size of a man's fist, two-thirds of which was incorporated in the uterine wall, the other third protruding posteriorly.

This woman received galvanism every day that she was not flowing, with few exceptions, for ten weeks. To be more explicit, she received forty-five treatments. The growth rapidly became absorbed. The menstruation at the first period was much improved. At the end of ten weeks the uterus was normal in size, and not a vestige of a thickening in the posterior wall could be discovered. All other symptoms disappeared, including the menorrhagia. It has been four months since treatment was discontinued. I saw the patient a month after she was discharged, and she was well.

The manner of application was as follows: A bulb uterine electrode (figure 5) connected with the negative pole was introduced into the uterine canal. The positive electrode was a large flat sponge electrode (figure 6), which was applied over the sacrum. At a few of the sittings I applied the negative electrode in the rectum opposite the tumor, applying the other on the abdomen. At each séance the current was made as strong as the patient would bear on the external surface. This varied from fourteen to eighteen milliampères.

Case 9 was also a young married woman, without children, who consulted me for irregular and painful menstruation, painful urination and backache. Age 29; six years married. She was anxious to bear children. This patient was first seen by me at the South Side Dispensary, Chicago. She afterwards consulted me at my office. Patient was well nourished and hearty, and presented no other difficulties than those of the pelvis. Local examination elicited the following condition: The uterus was large and crowded into the hollow of the sacrum. Protruding from the anterior wall and fundus was a large growth of firm, hard consistence, about three inches in diameter and about two and a half inches in thickness measured from the uterine canal. It seemed to be thoroughly incorporated within the uterine walls,

forcing the tissues either way, and presenting a convexity both anteriorly and posteriorly. The uterine canal was crowded upon and took a curved course around the tumor. It was with difficulty that the flexible probe could be made to pass it. The tumor protruded above the fundus, or at least lengthened the uterus in that direction.

The treatment in this case was substantially the same as that used in the above case. The bulb electrode was passed into the uterine canal until it pressed firmly upon the protruding tissue, and was held in that position. The external sponge electrode was pressed down firmly over the fundus of the uterus, including the growth in its grasp. The sittings lasted from fifteen to twenty minutes, and were, as a rule, given every day. The tumor reduced rapidly in size, the decrease being very noticeable from week to week. The patient was under treatment eleven weeks, receiving in all fifty-two treatments. The disagreeable symptoms that brought the patient under treatment had disappeared for some time, and it was with difficulty that I could induce her to come to me during the latter part of the time. She left me, at last, before I was quite satisfied with the result, although she was comparatively well.

The uterus was reduced to its natural size, measuring when treatment ceased two and one-half inches, instead of four and a half, as when treatment commenced. While there was a little thickening of the anterior wall noticeable upon careful examination, the tumor proper could practically be said to have disappeared. The menstrual difficulty had ceased. I have not had an opportunity of seeing this patient since last treatment, although she promised to report within a couple of months. As she was so well satisfied with the result of my treatment, I think that she would have reported if there had been any return of symptoms. It has been a little less than four months since treatment was discontinued.

Case 10.—This patient has been under observation for about two years. Electrical treatment was not adopted, however, until about six months ago. The patient is a robust young unmarried lady about 26 years of age. She consulted me because of an abdominal tumor. She had previously consulted a homœopathic physician who had Dr. R. Ludlam, of Chicago, see her. Both of the latter pronounced her incurable. Upon examination I found a large abdominal tumor attached to the whole anterior portion of the uterus, crowding that organ away from the bladder. The tumor pressed uncomfortably upon the latter organ, and filled the space between the uterus and bladder, in which position it could be easily felt through the anterior vaginal wall. The uterus was not enlarged. The tumor was ovoid, smooth, easily movable under the abdominal walls, about nine inches in its long and six in the transverse diameter. It was growing rapidly when she came to me. I advised an operation for removal by abdominal section. This she would not submit to until after other methods were exhausted. I therefore, with the idea of preventing further growth, if possible, by obstructing the circulation, gave her ergotine treatment. In connection with this the iodine

treatment was instituted. By these means I was able to prevent the growth of the tumor.

About six months since, after a lull in the treatment and considerable progress in the growth of the tumor, I commenced at the patient's request the galvanic treatment. The method was similar to that used in the two above cases. A uterine bulb electrode was introduced into the womb, or a vaginal ball electrode (figure 8) was introduced, and pressed firmly against the tumor where it rested against the anterior wall of the vagina, while the large hand electrode was pressed down over the tumor on the abdominal wall. From 10 to 14 milliampères are borne by the patient at each séance, which lasts from fifteen to twenty minutes. The treatment was repeated every second day for about three months, when the progress in growth was checked not only, but was reduced in size fully one-third. The treatment for unavoidable reasons was dropped for a month, when the tumor made rapid progress again in growth. The galvanism was commenced again and has been continued to the present time, with a still further diminution in the size of the tumor.

This case, I think, would have made much better progress if the treatment had been given every day instead of every second day. In a case in which the tumor is so large, situated as this is, with a texture so firm, I think the galvano-puncture is more suitable, and will give better satisfaction. The patient in this case was very susceptible to the current. She was only able to bear a comparatively weak current on account of a general feeling of depression which it produced. This was not noticed in the other two cases.

Thus, by the foregoing cases can be judged the advisability of using electrolysis in fibroid tumors. The method used in these cases I think originated with myself, though applications of the same principle in other conditions have been used by a number of operators. The method when properly carried out is reliable, prompt, painless, and absolutely free from danger. If for any reason it does not succeed, the failure does not preclude other methods of treatment. I therefore, knowing its results, very enthusiastically recommend it as a procedure well meriting careful consideration.

163 State Street, Chicago.

DISCUSSION.

DR. ELY VAN DE WARKER, of Syracuse, said:—Acting upon the suggestions of Dr. J. N. Freeman, I have used electrolysis in a case of large, rapidly-growing fibroid of the uterus. The patient, a young married woman, had a tumor extending nearly to the umbilicus. No menstrual difficulty. The patient was anæsthetized for the operation. A needle from each pole of the battery was inserted into the tumor. A current of from fifteen to twenty zinc carbon cells from an ordinary galvanic battery was employed. Notwithstanding the anæsthetic, the patient writhed with pain. Following the operation in about three days a high temperature was observed, which was

found to be caused by an abscess forming. This abscess in time evacuated itself.

In three months, at a séance of thirty minutes' duration, a much stronger current was used. A subsequent examination exhibited no improvement in the case. In two other cases similar treatment was employed with like results. The treatment in my hands has proved very painful, and not entirely free from danger.

DR. ROBERT NEWMAN, of New York: Congratulating the author on his excellent paper, I feel my inability to discuss it, as I can only coincide and approve the contents in every particular, finding no point to differ. My object in rising is rather to dissect the discussion, illustrating some points and adding to it some of my own experience.

If the last speaker and others have failed in electrolysis, and particularly in the treatment of fibroids, it is due mostly to using too strong a current. Electrolysis may be applied in different degrees of strength, either to absorb, or destroy, tissues. In most cases we use it for absorption, and in such cases weak currents *must* be used. I have always insisted on such currents, and long intervals between séances, and cannot repeat too often as a guide to success, the advice, "weak currents and long intervals." Some operators report the use of from twenty to even seventy and eighty cells. Such heroic efforts appear almost criminal, and it is a wonder that fatal results have not occurred after such treatment; and still more surprising is it that some report successes. The treatment of tumors, and particularly fibroids, is a wide field for investigation, and I have no doubt will result in favorable reports in the future. At present there is a diversity of opinion in the profession on this point. Failures may occur, for good reasons, as, bad management, bungling in the operation, using defective instruments, wrong diagnosis, too strong a current, operating at a wrong time, or too frequently, or by a wrong method, etc. For instance, I consider it wrong to use needles at both poles inside of a fibroid, and have seen bad results by using one needle, which was insufficiently insulated, in the tumor. In the latter case the current burned along the whole track of the needle, and caused thereby a peritonitis.

If needles are used it is best to introduce the needle as the negative pole into the tumor, so well insulated that only the point acts upon in the tumor, while the peritoneum, and other tissues outside the tumor, are not affected by the electricity. The positive sponge electrode is held near the tumor on the cutaneous surface. There are many other methods used and reported by different authors.

It is admitted that premature and reckless statements, as also failures in such cases, have shaken the belief of many, and created a skepticism in the profession. But that is overbalanced by the accumulation of positive evidence of successful reports and cures by trustworthy men, who can furnish witnesses and produce the patients so cured; for instance, Freeman, Everett, Apostoli, Menière, and many others. We have also on record brilliant cures of ovarian tumors by Ehrenstein, Clemens, VanDer-

veer, and particularly by Lemeleder, of Mexico. The latter confirms his successes in a letter which I received from him recently, and adds new cases to the list. The indurations left after pelvic cellulitis I have often removed entirely by repeated applications of electrolyses: which would not have yielded to any other treatment. In these cases I also used weak currents repeated once a week.

In carcinoma I have had successes and failures. In such cases I use the electrolysis as a destructor of abnormal tissues, and therefore must apply strong currents. A negative needle is inserted at or near the periphery of the tumor, while a positive sponge electrode is applied opposite on the cutaneous surface. Séances are repeated in short intervals until the tumor is destroyed. The success depends on whether the circle operated on has included the whole region of the carcinoma. If cancer-cells have extended outside of that circle, and are left to proliferate, the case will end fatally.

And now, Mr. President, I add to the list the greatest achievement of electrolysis, the certain saving of every woman afflicted by *extra uterine pregnancy*, while all perished in former times. Successful cases have been reported by A. D. Rockwell, E. G. Landis, Nathan Bozeman, Garrigues, Reeve, Lusk, and others. The *modus operandi* is simple. Repeated applications, one metal pole in vagina or rectum, near and below the tumor, the positive sponge-electrode above the abdomen, will destroy and absorb the foetus. It is of great importance to the obstetrician, nay, to every practitioner, to know that he has a certain remedy to save life in this troublesome anomaly of nature.

I have also used electrolysis successfully in vaginismus, strictures of the rectum and urethra. The latter diseases are rare in females, but they occur.

In conclusion, I wish to say that it is desirable to express the amount of electricity used in definite terms; that is, to measure it. If I have reported cases in which I said I use six cells, etc., it has been done for the purpose of being better understood by the non-expert, and partly because we have no instruments which express exactly the measure, as our present galvanometers are not exact, too expensive, and in many cases in reality are only galvanoscopes. Time will come, and I hope very soon, when we will have good, reliable instruments, obtainable at a reasonable price, which will measure the electricity exactly.

DR. GEO. F. HULBERT, of St. Louis, said: I am a great advocate of electricity. I have even been called an electrical crank. I am surprised that Dr. Van de Warker should use electricity without a means of measuring it. As well use strychnine or quinine without measuring the dose, as to use electricity without measuring it with the galvanometer.

I have recently used electrolysis in a case of chronic pelvic abscess, with complete success. With Dr. Engelmann I have seen electrolysis employed for fibroids of the uterus with gratifying results. Much is to be hoped for from this treatment in gynecological practice.

DR. GEORGE J. ENGELMANN, of St. Louis, said:

Gratified as I have been by the progressive spirit evinced by the labors of Dr. Martin, pleased as I have been to hear of the results he has achieved, yet I have been greatly surprised. I am surprised to hear my friend Dr. Van de Warker, one of our most progressive gynecologists, tell of his patient, though under the influence of an anæsthetic, *writhing in agony* from pain caused by the galvanic current in efforts at electrolysis! I am surprised to hear the gentlemen, especially Dr. Newman, so well known in the field of electro-therapeutics, gauging the force of the galvanic current by the *number of cells* used; and I am surprised also to hear the sensation of the patient spoken of as the limit or measure for the strength of the current. This is the teaching of the past, using the electrode externally, *upon* the tissue to be affected, limiting the strength of the current by the sense of pain experienced by the patient, and expressing the force used in the number of elements needed to destroy it; this current is necessarily a weak one, and to accomplish anything long sittings are needed.

The success of the electric treatment, galvanic or faradic, of to-day—perhaps I should say of the future—is based upon the precise dosing of the remedy, the use of powerful currents, for a short time, but applied *in loco* to and into the tissues. I have followed the footsteps of that able Frenchman, Apostoli, to whom we owe this new departure in electro-therapeutics, and it is my opinion, based upon his success and my own results, that the electric forces, when correctly gauged and directly applied, will prove an invaluable aid in gynecological treatment.

Dr. Martin tells us of a uterine fibroid, of the size of an apple, reduced after six or eight weeks treatment, sittings of twenty to thirty minutes each, repeated every other day.⁵⁰ I have destroyed uterine tumors, somewhat smaller, indeed, the largest the size of an egg, in *three* sittings of *five minutes* each, causing the patient no pain. I have reduced to less than one-third of their original size, uterine fibroids filling the pelvis and extending above the navel, in from ten to twelve sittings of five minutes each, treating the patient in my office or clinic, using no anæsthetic, and causing no excessive pain. Remember, that for the destruction of these large tumors I used the galvanic current not longer than fifty minutes or one hour, as long as Dr. Martin does in two or three sittings, but I know precisely the remedy administered. To attain a certain purpose, a certain dose is necessary; for the reduction of a fibroid, we needs must have more than for the treatment of a simple hyperplasia. As a certain dose of morphia, varying slightly with the individual, is necessary to ease pain, and another to produce complete loss of sensation and sleep, so it is with the galvanic current.

The strength of the current must be gauged *by the object to be accomplished*, and *not by the feelings of the patient*, as has been the custom, and by the kind of electrode used we prevent unnecessary pain. The galvanic current must be dosed as we dose other remedies, and in proper dose it must be applied directly to the proper place; definite results may then

⁵⁰ The longest sitting I have advised is twenty minutes.—Martin.

be expected. The vague manner in which electricity has been used I have always compared to the rubbing in of quinine for the cure of malaria; unless we give certain doses, at certain times, no decided result is accomplished; in time it may do some good. So it is with the galvanic current; by the long-continued use of the mild currents, sittings of twenty or thirty minutes, every few days, some good will result; but until the galvanometer becomes a part of the galvanic battery, and until currents of known strength are applied directly to and into the diseased tissues, progress in the field of electro-therapeutics is impossible.

A SUPPLEMENTARY PAPER TO DR. MARTIN'S, CITING TWO CASES OF FIBROID TUMOR SUCCESSFULLY TREATED BY ELECTROLYSIS.

BY J. N. FREEMAN, M.D.,

OF BROOKLYN, N. Y.

The electrolytic treatment of uterine fibroids has now been so long before the profession, so thoroughly tested, and so entirely successful, that it is entitled to a place among the recognized means of dealing with these troublesome growths. Fatty tumors have not, in my hands, yielded to its influence, nor have I succeeded in curing cystic tumors; but fibrous growths will uniformly melt away and be absorbed under a proper application of the constant current. The most suitable cases are those intramural or sub-peritoneal fibroids where ergot is useless, and where, without this resource, we could only hope to cure our patients by removing the uterine appendages or the uterus itself. To illustrate my methods of treatment, I will give two cases in detail, the first of which was read before the Medical Society of the County of Kings, at its regular meeting in June, 1878. The other case has not been reported:

Case 1.—Miss O., aged 35, came under my care in St. John's Hospital in May, 1876. Anæmic, and suffering from extreme nervous debility. Menstruation profuse and painful. Examination revealed a fibroma of the right anterior wall of the uterus, more nearly approaching the peritoneal than the mucous surface. Ergot had been used persistently and in large doses, without benefit. A consultation having decided that no surgical interference was admissible, I determined to attempt the destruction of the tumor by electrolysis.

The first operation was on December 23, 1876, and was done in the presence of Dr. Jos. C. Hutchison, Dr. Wm. Gilfillan, Dr. J. H. H. Burge, Dr. J. R. Bird, Dr. Frank W. Rockwell, Dr. G. G. Hopkins, Dr. A. W. Catlin, Dr. E. S. Bunker, and Dr. Charles Corey. The uterine cavity was found to be five and one-half inches in depth. The tumor was plainly mapped out through the abdominal walls, and apparently of the size of the head of an ordinary child at birth. After she had been placed under the influence of ether, I took a large sail-needle, curved at the pointed end, and insulated to within an inch of the point, and, passing it through the cervical canal, thrust it into the tumor and connected it with

the positive pole of a galvanic battery. A straight round needle, similarly insulated, was then thrust through the abdominal wall and into the tumor, taking care to avoid the bladder, and so placed as to come within an inch of the other needle, and then connected with the negative pole of the battery. The tumor was so dense and firm as to require very heavy forceps and much force to drive the needle into it. A current from sixteen cells was continued through the needles for fifteen minutes. No unpleasant effects were experienced; and the patient was out of bed the next day.

I repeated the operation in the same manner on January 2, 1877, continuing the current for twenty minutes, and again on January 9, this time increasing the number of cells used to twenty-four, and the time to twenty-two minutes. The next week her menstruation was less profuse and less painful than usual. I repeated the operation February 6 and 12, increasing the time to half an hour and using thirty-two cells.

March 6, before the sixth operation, the uterus measured four inches and a half in depth. The tumor, or what remained of it, was soft to the touch, and the needle could be easily passed in any direction through it with the fingers. Her general health was much improved. The seventh operation was Mar. 12.

April 3 the sound passed into the uterus only to the depth of three inches and a half. This, the eighth and last operation, was unfortunate, as the needle that was passed through the abdominal wall was stripped of its insulating covering and the track of the needle so much irritated as to cause an abscess that was slow in healing.

I left her in the hospital in June for a long trip in the East, and did not return for eight months, during which time she had no medical treatment. On my return I made a careful examination, and found no trace of the tumor. The sound would pass but two inches and a half into the uterine cavity, and the uterus was freely movable in the pelvis. I have examined the lady at least once a year since that time, and saw her only last week in excellent health and with no symptoms of ever having had any trouble in the pelvic cavity. Her menstrual periods are regular as to time and quantity, and are painless.

My *fifth* case was referred to me on Feb. 12, 1885, by my friend Dr. Alexander S. Clark.

Case 5.—Mrs. H., aged 31; married six years; no children. Menses always scanty and painful. A fibroid tumor, the size of a large cocoanut, occupied the anterior uterine wall. The cavity of the uterus measured five inches and a quarter in depth. The tumor was attached by its entire anterior surface to the bladder, preventing contraction of that organ to expel the urine, and thus causing a severe chronic cystitis. This lady was very much debilitated, and not able to leave her bed without assistance.

In this case I operated three times, February 16, April 29, and June 4, 1885, using for the positive pole a platinum probe, not insulated, passed to the fundus of the uterus; and for the negative pole, the straight, insulated steel needle, passed through the anterior wall of the abdomen, and into the tumor. I used thirty cells for about half an hour on each occa-

sion. The tumor was quite soft and two-thirds gone at the time of the third operation, and her health had steadily improved.

In September she walked from her house to my office and back, the distance of a mile each way, and has been in fair health since. The action of the uninsulated probe in these operations produced enough irritation to partially occlude the cervical canal, which needed some after attention. The uterus is now freely movable in the pelvis, is of the normal size, and has no remnants of the tumor. The bladder has entirely regained its healthy tone.

I have now treated eight cases, and have seen cases treated by other surgeons with my needles, and from this experience have come to the following conclusions:

When the tumor is sub-mucous or intra-mural, the positive pole should be attached to a curved platinum needle, insulated to an inch from the point, and which has been passed through the cervical canal and thrust into the tumor. This course may be followed in sub-peritoneal tumors if the base is broad enough to be sure of inserting the needle into the tumor, and not one side or beyond it.

In other cases, or where the tumor is sub-peritoneal, with a narrow pedicle, the positive pole should be connected with a large platinum probe, insulated to an inch from the end, to be inserted to the fundus of the uterus or to the vicinity of the base of the tumor. In all cases the negative pole of the battery should be connected with a straight, round, smooth steel needle, strong enough and properly tempered not to break, and insulated to one-half or three-quarters of an inch from the point, and this thrust into the tumor from the most available point, whether through the vaginal walls or through the abdominal parietes, taking care not to wound the intestines nor the bladder.

Sixteen to thirty of the ordinary zinc-carbon cells is as strong a current as I would advise, and from fifteen to forty minutes the limit of time. An anæsthetic is always required. It is better to give plenty of time between the operations than to be in too great a hurry. Once, or at most twice, between the menstrual periods is often enough, and if there is much reaction, that may be too often.

I have had no experience in treating those immense fibroids measuring twelve inches or more in diameter, that we occasionally see, but am confident that they can be cured, in the large proportion of cases, if taken in the earlier stages, at the time when they usually come under the notice of the physician.

80 Hanson Place, Brooklyn, N. Y., June 26, 1886.

POTASSIUM CHLORIDE.¹

BY ASA F. PATTEE, M.D.,

OF BOSTON, MASS.

Nothnagle and Rossbach, in their "Treatise on Materia Medica," say that "therapeutically potassium

chloride is not used." We find no mention of its use in the United States Dispensatory, National, or the various works on materia medica. Sander has recommended its use in epilepsy in place of the potassium bromide. Opinions vary as to its usefulness in that disease. It has its place, however.

Potassium chloride closely resembles common salt in appearance; it crystallizes in anhydrous centres; permanent in air, soluble in three parts of cold water; has a simple saline taste not as pronounced as common salt.

Formerly it was generally considered that the corresponding salts of potassium and sodium had the same physiological and therapeutical action upon the animal body; and it was a matter of indifference which salt was used. It is now known, however, that this is by no means so, and that important and well-defined distinctions do exist in the two salts.

In the body the potassium chloride is found in the tissues, cells and blood-corpuscles, while in the fluids (the serum of the blood, lymph and bile), we find almost exclusively sodium chloride. Arterial blood mixed with a dilute solution of potassium chloride becomes brighter than that mixed with a solution of sodium chloride. Potassium chloride given in 20-grain doses with 15-grain doses of sodium chloride three times a day after meals, causes an increase in the molecular tissue and red blood corpuscles, a fact that I myself have proved.

The effect of potassium, citras and acetates when introduced into the system, is to cause the excretion of a large amount of sodium chloride in proportion to the amount given. The potassium chloride does not interfere with the normal amount of sodium chloride in the fluids or solids of the body.

That potassium chloride is essential for the development of the animal tissues is shown by the fact that food which in itself is not sufficiently nutritious, such as over-boiled meat, recovers its properties on the addition of potassium chloride and a small portion of sodium chloride (Binz). Experiments with plants show also how necessary potassium is for cell nutrition.

For many years I have used potassium chloride, and find it a valuable medicine either alone or in combination with other medicines. I have used it in many cases of anæmia after other well-known treatment had failed to do good, with the most happy results. The dose usually given was 5 grains every three hours in a wineglass of water. In the commencing stage of cirrhosis of the liver due to alcoholic excess it has apparently been of benefit.

Exudations after inflammation with effusion of lymph, particularly pelvic cellulitis, have quickly disappeared under its use. In glandular enlargements, in my hands it has been of more benefit than calcium chloride or the iodine compounds. In stomatis of pregnant women or from mercury it is equal to the chlorate. In ovarian neuralgia with nervousness and menstrual headache accompanied with wakefulness, this salt has given better results than the bromide or ammonium chloride. When combined with corrosive sublimate it is one of the best preparations for syphilis. I usually give it as follows:

¹Read in the Section on Practical Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

- R. Potassii chloridi. 3ij.
 Hydrargyri chlo. corros. gr. i.
 Aquæ. 3iv.
 M. S. 10 to 20 drops every two hours in wineglass of water.

This preparation I have used almost exclusively in the treatment of syphilis in both its acute and chronic stages, and the result has been most satisfactory. The tincture ferri chloridi is much improved in its therapeutic action when given with potassium chloride.

It is my desire that those of our profession who have not used the potassium chloride may investigate its therapeutic action, of which I can assure them it will verify my statement. The dose will range from 20 grains to 2 drachms in the twenty-four hours, well diluted with water.

EMBOLISM.¹

BY J. W. THOMPSON, M.D.,

OF ST. PAUL, MINN.

The detachment of fibrinous deposits from the interior of the heart is an occurrence so thoroughly recognized and understood by the profession, that it seems almost superfluous for me to invite your attention to this subject. The cases to which I desire especially to direct your attention, contain nothing that has not been carefully canvassed by more competent observers than myself. Yet aside from the interest they may possess for the ophthalmologist, they are sufficiently rare from a broader standpoint to possess also much interest for the general practitioner. It could scarcely be considered a presumption in me to believe that you will readily pardon me for being found occasionally outside of the strict limits of my specialty, discussing matters that are of vital interest to both you and me. The links that connect diseases of the eye with systemic diseases are numerous. To understand and to treat diseases of the eye intelligently and successfully, require a theoretical and practical knowledge of the treatment of systemic diseases.

Embolism is only a symptom and it is not infrequently seen by the ophthalmologist in the early stages, from the very fact that small arteries, such as the retinal, are often obstructed first. The very circumstance of the existence of an embolism, whether it be of the retinal artery or of any other, presupposes at least a disease of the heart or large arteries. One of the cases to which I shall directly invite your attention proved to be only a symptom of an existing endocarditis. In this disease paresis of the heart constitutes the actual danger while valvular lesions form the ultimate danger. In the beginning of endocarditis, before there has been any detachment of vegetations to obstruct even small arteries, the functional disturbances and subjective symptoms have no well marked characteristic features. The most of them appear either isolated or combined in other diseases of the heart and its envelopes, or even in the affections of distant organs. It is then upon the physical signs alone that a diagnosis can be founded,

since the antecedent symptoms can only furnish presumptive evidence as to the nature and seat of the lesion. The symptoms of endocarditis and pericarditis so closely resemble one another that they may be confounded and can only be accurately distinguished by means of auscultation. The auscultatory signs by which a differential diagnosis can be determined are as follows: "In endocarditis the murmur is synchronous with the first sound of the heart, and does not occur with the diastole unless regurgitation takes place through the aortic or pulmonary semi-lunar valves, and the murmur is heard loudest at the apex of the heart." "In pericarditis the murmur is not exactly synchronous with the valvular sounds, and often occurs during both the systole and diastole of the heart, and the murmur is heard loudest at the border of the sternum near the fifth left costal cartilage."

This affection of the heart is frequently caused by rheumatism, chorea, pyæmia, or the acute exanthematous fevers (Ingals). In endocarditis numerous vegetations accumulate on the surface of the aortic or mitral valves. These vegetations become detached and float about in the circulation, occasionally plugging up small arteries, and when large enough larger arteries become obstructed by them. The secondary affections that may result from this infarction of different arteries by these detached vegetations are loss of vision from obstruction of retinal artery, gangrene of a leg or an arm by cutting off the circulation, swelling and inflammation of the spleen, acute atrophy of the liver, pneumonitis, cerebral disease, etc.

Case 1. A man, Mr. L. C., aged about 30, of very stout build, a carriage ironer by occupation, and with an excellent family history on both sides, consulted me on account of a very sudden blindness of his left eye. Up to this time he had enjoyed very good health with the exception of a slight attack of rheumatism which had occurred a few weeks before I saw him. From this, however, he seemed to have fully recovered. On ophthalmoscopic examination I observed the very characteristic appearances of an embolism of the retinal artery. The optic disc was quite pale and transparent, and the arterial vessels thin, and here and there changed into white bands with an occasional red plug of coagulum. The media was quite clear. In the course of a week or ten days there was a well marked improvement, absorption having taken place and the circulation in the retina began to be reëstablished with a return of a considerable amount of sharpness of vision. In the course of a week or ten days vision in this eye had so far advanced that he could see to go about very comfortably. The other now became affected in a like manner and pursued a similar course. When this one began to improve, the one first attacked had very nearly recovered full sharpness of vision. Examination by auscultation revealed, but not clearly, what seem to me to be an endocarditis. I consulted a brother practitioner for whose opinion I entertained much respect, and he confirmed my diagnosis.

In a few weeks the physical signs of endocarditis became better marked, when he was suddenly seized with a severe pain in his right arm which extended

¹ Read before the Minnesota State Medical Society, in Minneapolis, June 17, 1886.

from a short distance above the elbow to the wrist and hand. I was called to see him in bed very much prostrated with the pain. The arm was much cooler than its fellow and almost or quite pulseless. There was a knotty tumor in the brachial artery near its bifurcation. The circulation in the radial and ulnar arteries was entirely cut off. For the relief of the pain I employed a hypodermic injection of morphia, applied warm, stimulating embrocations and encased the arm in cotton-wool. I prescribed large doses of bicarbonate of potash with a view of rendering the small pieces of coagula that might yet be floating about in the circulation more soluble. The next day, notwithstanding the arm had been maintained in the horizontal position and kept under the bed-clothes with the application at intervals of every hour or two of warm stimulating embrocations, was quite pale, cool, shrunken and pulseless. In short, the vitality of the limb was with difficulty preserved through the timely efforts of the anastomosing branches. The recovery was slow but upon the whole satisfactory. The pulse by degrees returned, but up to the time I saw him last, which was two years from the date of the attack, was perceptibly feebler than in the left arm. This arm he informed me, always became cold much easier than the left, and in consequence of this he was obliged to keep it clothed warmer than its fellow. The strength had very materially increased so that he could support nearly as heavy weight with it as with the other, but for a much shorter time.

Case 2. Mrs. E. H., a married lady, 27 years of age, became a patient of mine in October, 1865. She had been under the care of a neighboring physician for some weeks. Since he expected to be absent from home for a protracted period, he requested me to take charge of her case. He informed me that about four weeks since she had aborted at or near the fourth month of gestation. The placenta had never, to his or the patient's knowledge, come away *en masse*. As a result of this she was then suffering from septicæmia, which confined her in bed for a period of five or six weeks from the first date of my attendance. Several large abscesses formed in the region of the hips. During this time she became very suddenly blind in her right eye. The sight of this eye was never recovered. A subsequent ophthalmoscopic examination demonstrated that this had been the result of an embolism of the retinal artery.

In about four weeks from the date of the loss of the eye, she had sufficiently recovered health and strength to enable her to be out of bed and about the house a good share of the day. At her urgent request her nurse gave her a warm sponge bath. The next day I was called to see her and found her pulse somewhat over 100, her tongue tremulous and slightly furred, her bowels constipated, and her skin hot and dry. The sounds of the heart were normal. In the lower part of the right leg there was but little feeling. The foot was cold, shrunken and livid. At the lower end of the middle third of the femur there was a hard knot or tumor which was sensitive and painful. There was no circulation in the limb below the tumor. The pulsation of the femoral artery above the tumor was very feeble and easily compressed. This state of af-

fairs continued for five or six days when the limb below the knee became gangrenous. The line of demarcation formed close to the knee joint. She was at this time considerably reduced in strength, and I entertained very serious doubts as to her recovery or even her ability to survive an amputation of the limb. By the request of the patient's relatives the late lamented Dr. W. H. Mussey, of Cincinnati, was called in consultation. Notwithstanding the very much reduced condition of the patient's strength, he advised the immediate amputation of the limb well above the line of demarcation. He also entertained very serious doubts as to her surviving the operation, but of course, it was the only procedure that offered the slightest prospect of relief. Accordingly the limb was amputated. Before tying the arteries plugs of coagula one or two inches in length were drawn out of each artery. The stump did badly for two weeks, discharging large quantities of pus. The flaps sloughed some but finally united. The sloughing and suppurating gave rather an unsightly appearance to the stump, but it finally became sound and proved to be a very useful one. The patient became hearty and robust, and continued to increase the number of her family for several years thereafter.

The cause of the embolism in this case seemed to be due directly to the septicæmia, since there never appeared any heart complication. Dr. Mussey reported the case in a clinical lecture to his class in the Miami Medical College. I preserved his remarks for a long time, and thought when I commenced preparing this paper that I should be able to avail myself of his valuable observations, but the document had become misplaced, and I am obliged to forego both the pleasure and the profit thereof. Perhaps some of the older members present may have seen his report and remember more of the details than I have recited. I have often debated the subject in my mind whether the warm sponge bath had any direct agency in producing the embolism, or whether they were only contemporaneous events.

MEDICAL PROGRESS.

A NEW EXPLANATION OF THE PROCESS OF MENSTRUATION.—LEWENTHAL (*Archiv. für Gyn.*, B. xxiv, Hft. ii, 1884), in an exhaustive article, gives a new theory of menstruation which shows marked originality and research. It would be impossible, in the short limits of this report, to give an abstract of the elaborate train of reasoning by which he arrives at the results. They are summed up briefly at the end, and we would refer those interested in the subject to the article itself for the minute details. He makes the following propositions:

1. The periodical flow of blood from the female genitals is not a consequence of the rupture of a follicle (which usually occurs at the same time), but of the degeneration of the uterine mucous membrane, which has become hypertrophied before such rupture, and independently of it.

2. This growth, the menstrual decidua, is caused by the imbedding in the unimpregnate condition of the last ovum furnished by the ovaries.

3. If this imbedded ovum is impregnated, the menstrual decidua becomes that of pregnancy, but if the ovum remains unimpregnated, it degenerates as a consequence of the death of said ovum.

4. Taking each menstruation for itself, the rupture of the follicle and the flow of blood stand in another causal relation to each other in that possibly the causes and conditions which are operative at the occurrence of the hæmorrhage may, at the same time, have an effect in bringing about the rupture of a ripened follicle.

5. The coincidence of the rupture of a follicle and the flow of blood is, therefore, no necessary one. Each can occur separately; a follicle can rupture without there being any menstrual decidua present, and this secondary consequence of the ovum, which has previously made its appearance—namely the menstrual flow, can occur without a new follicle rupturing at the same time.

6. The periodicity of menstruation is determined by the extra-follicular life of the unimpregnate and imbedded ovum; the variations from the general or individual periodicity depend upon the shortening or absence of such capacity for life, either idiopathic or the result of intercurrent influences.

7. The ovum which has been expelled, usually at the last menstruation, and is present ordinarily in the uterus (in abnormal cases elsewhere), is the one which is impregnated. From these the following practical conclusions can be drawn:

8. Since the menstrual flow is neither a physiological function, nor the necessary accompaniment of such a function, but the direct consequence strengthened by innumerable repetitions of a process which is the result from social conditions—namely, the unimpregnation and death of the human ovum, therefore it has all the properties and results of other hæmorrhages which are always pathological.

9. It increases and diminishes under like conditions with them.

10. The flow of blood which is the necessary accompaniment after menstrual decidua, is only to be regarded as harmless when it occurs *per diapedesin*. When *per rhexin*, it is under all circumstances unnecessary, and becomes injurious when it is felt and responded to by the entire organism as a loss.

11. The amount of the injury corresponds to the proportion between the amount of blood lost, and the quantity (plus the quality) of blood which the body contains at the time.

12. Under these circumstances the indication is for the greatest possible reduction in the amount of the menstrual flow, as of any other loss of blood.

13. The means to be recommended are first and foremost rest in bed, and hot water injections.

14. On the contrary, the voluntary cessation of the menses (idiopathic amenorrhœa), is under no circumstances to be regarded and treated as a disease, it is only a sign that a function (ovulation) which is not necessary to the life of the individual, from some cause or other (youth, age, pregnancy, lactation, de-

bility), was not properly performed at the proper time, that is about four weeks previously.

15. Supported by this theory, and the observation of Lawson Tait as to the importance of these tubes for menstruation, it would be desirable to substitute for castration, salpingotomy (partial resection of both tubes after previous ligation) in those cases where uterine dysmenorrhœa, menorrhagia, fibroids, and such uterine affections call for the anticipation of the menopause.

16. Should it appear impossible after beginning the operation for castration in the above mentioned conditions, to completely remove the ovaries, salpingotomy would be directly indicated.—*Glasgow Medical Journal*, May, 1886.

THE BLOOD IN LEUKÆMIA, TOGETHER WITH OBSERVATIONS RELATING TO THE ORIGIN OF THE FIBRIN FERMENT.¹—According to the ideas of Alex. Schmidt, fibrin is formed in the coagulation of blood and serous fluids by the action of three substances. One of these exists formed in the fluid; it is regarded as the groundwork proper, and has been called fibrinogen. The other two, called respectively the fibrinoplastic substance and fibrin ferment, are presumably derived from the white corpuscles, that are destroyed and are formed at the time of coagulation. In this destruction of the leucocytes there is supposed to be an interaction of the blood plasma and the protoplasm, in which the former takes from the last the constituents necessary to form the fibrin element.

In some cases of failure of the blood to clot, it has been regarded as due to an insufficient breaking up of the cells above mentioned. In other words, there is blood in which all the stuff necessary for the formation of the ferment is present; but in which this never is made, because the blood plasma has been so altered as to be deprived of its destructive agency.

One author thinks this to be the case in blood in leukæmia. From the standpoint of Dr. Schmidt this would not be expected, as from the large amount of white cells the action should be very energetic.

In order to prove which view was correct, blood was drawn from a leukæmia patient, in which were 2,000,000 red and 630,000 white corpuscles to a cubic millimetre. The venous blood did not coagulate particularly slowly, but the fibrin was poorly developed, soft, and did not contract firmly. On a further addition of leucocytes the time of clotting was prolonged. On the other hand, that of filtered plasma from the horse was greatly accelerated by the addition of one-seventh of its volume of leukæmic blood.

In the blood from the cadaver of this patient only traces of the free ferment could be detected with the proper reagents. If instead of the entire blood only the white corpuscles, which were deposited on standing, were alone added to the horse's plasma, the time of its coagulation was much retarded. From these experiments the author concludes that in reality the groundwork for the development of fibrin ferment was present in the leukæmic blood, but that its plas-

¹ J. v. S. Himmelstjerna. Fortschritte der Medicin, 1885, p. 669.

ma could not form the true ferment out of this as in the normal plasma of the horse.

In the leucæmic blood the formative materials of the ferment are kept attached by the white corpuscles. But from the investigations of the author they were found in solution in fluids that are capable of coagulation. Examination of the filtered plasma before and after this showed that the amount of ferment was greatly increased during the process. Since the formed elements were wanting here, the fibrin must be formed entirely from substances in solution. The action of a fluid obtained from a hæmorrhagic cyst in the neck also favored this view. It contained but few cells and did not coagulate spontaneously. Nevertheless, filtered normal plasma separated considerable quantity of the ferment from this. The filtered fluid also acted on the horse's plasma not only in shortening the time of coagulation, but also by increasing the amount of fibrin formed.

The author finally turned his attention to a consideration of the nature of the substance which formed this substratum of the ferment, and he concludes that it comes from the retrograde metamorphosis of the albuminous bodies. He tried, therefore, if the addition of any of these bodies would accelerate the process. The results obtained in this way were variable, but on the whole were in accordance with the theory. The experiments were more successful, however, when conducted in the following way: A solution of one per cent. of glycocholate or taurocholate of soda was added to the filtered plasma, which entirely deprived it of its spontaneous coagulability. If to this one of the above mentioned products be added, fibrin is formed in a few hours. Whether these are themselves the sources of it, or whether they simply increase the activity of that already in solution (by decreasing any resistance) is left undecided by the author.—*Boston Medical and Surgical Journal*, May 27, 1886.

THE SALICYLIC TREATMENT OF GLYCOSURIA.—From his recent researches, PROF. LATHAM concludes that there are two distinct kinds of diabetes. First, there is that which arises from a neurotic disturbance of the function of the liver; this has the effect of arresting the metabolism of the glucose, and allowing it to pass unchanged into the general circulation and appear in the liver. Second, that which arises from a neurotic disturbance of the function of muscle; this allows glucose to form in that tissue, and to pass unchanged into the general circulation and appear in the urine. He has also shown that this second kind of diabetes is intimately connected with rheumatism; so intimately, that a degree of more or less oxidation determines whether the muscular tissue generates an abnormal amount of lactic acid or of glucose in the system. Moreover, he has shown that when salicylic acid is administered, it has the property of arresting the formation of both lactic acid and glucose, by means of a chemical combination which it forms with the antecedents of these products.

These views are to some extent confirmed by an article published in the *Therapeutic Gazette* of last year, page 446, by Dr. Thomas J. Yarrow, in which

are outlined four cases of the complete disappearance of sugar in the urine under the continuous administration of salicylate of sodium. In the *British Medical Journal*, May 1, 1886, Dr. Holden in a very valuable article calls attention to the rheumatic glycosuria, and reports six cases of rheumatic glycosuric patients in all of which the administration of salicylic acid produced a great reduction in the quantity of urine and entirely removed the sugar. In several of these cases there was no restriction in diet ordered. Dr. Holden has also used salicylic acid in four other cases in which no rheumatic symptoms existed, and in all failed to make any impression on the polyuria or sugar. The first and most marked effect of the salicylic treatment, according to Dr. Holden, in the glycosuria of rheumatic persons, is the almost complete removal of the distressing polyuria which accompanies it.

As to diet, the careful restriction which is so imperative in the diabetes of hepatic origin is not so necessary in this kind; still, Dr. Holden thinks it greatly helps to restrict the formation of glucose in the system, by prohibiting potatoes, farinaceous puddings, and sugar as much as possible.

In administering salicylic acid, the following mixture has given good results: \mathcal{R} . Salicylic acid, 3ii; bicarbonate of sodium, 3i; carbonate of ammonium, 3i; mix in water, 3i; and, when effervescence has subsided, add water to 3xii. One-eighth or one-twelfth part to be taken three times a day. This is a soluble neutral mixture, and is not unpalatable when given in a wineglass of water, with a little tincture of orange peel added. The ammonia prevents any depressing effects. Dr. Holden has tried the free acid made into 3-grain pills with mucilage, as recommended by Dr. Latham in rheumatic fever, but has not found them superior to the mixture, while patients object to swallowing five or six pills as a dose.

It is a matter of much importance, with regard to treatment, to be able to distinguish between the two kinds of diabetes. The presence or absence of rheumatic arthritis, pains, and cramps, is often sufficient; but Dr. Latham has recently called attention to a more certain mode of distinguishing between the two, as he has found that in the diabetes of rheumatic persons—that is, originating in the muscular tissue—the urine contains some substance which dissolves cuprous oxide; so that a larger quantity of Fehling's test has to be added before getting the brown precipitate in this urine than in the diabetic urine of hepatic origin.—*Therapeutic Gazette*, June 15, 1886.

TEREBENE AS A GENERATOR OF OZONE.—In a recent note on this subject, DR. A. M. McALDOWIE says: The treatment of lung diseases by inhalation is beginning to be adopted by the profession at large. It has been for years my favorite method of treatment, in a district where, unhappily, pulmonary complaints are unusually abundant. In the *British Medical Journal* for 1881 (vol. ii, p. 666), I stated that, after four years trial, I had adopted terebene in preference to other antiseptics, and had administered it

both internally and by inhalation in over two hundred cases of phthisis, bronchiectasis, chronic bronchitis, and other pulmonary complaints characterized by profuse purulent expectoration. Further experience has strengthened this opinion. In connection with this subject, I wish to call attention to a point which appears to have been overlooked by recent writers on the subject, namely, the formation of ozone which attends the slow oxidation of the various members of the turpentine group. When I went to reside at the North Staffordshire Infirmary, ten years ago, I was struck with the remarkable success which attended the treatment of chronic lung diseases; a fact which I at first attributed solely to the elevated site of the hospital. But I afterwards noticed that there was a high percentage of ozone in the atmosphere, especially when the wind was from the west, where there are extensive tracts of pine woods. It is well known that the air in pine woods contains a large amount of ozone. Mr. W. Goss, a pottery manufacturer in Stoke, informed me that he had noticed that the men and girls employed as enamel painters were exceptionally healthy compared with the other pottery workers, although the hygienic conditions were mostly unfavorable; the painting having to be done in hot close rooms. He attributed this entirely to the turpentine, which is used as a medium for mixing the colors. Spirit of turpentine is exposed in the room, in flat leaden vessels, where it speedily oxidizes. Part of the oxygen liberated attacks the vessel, which becomes coated with oxide of lead; the rest escapes into the atmosphere in the form of ozone. Pursuing this subject still further, I have made inquiries at several small shops where paraffin is sold, and have found that the inmates are unusually healthy and fresh-looking, considering the bad hygienic construction of their dwellings. I have likewise found two cases where the vendors had previously suffered from chronic chest disease (consumption, they told me), and had taken to selling paraffin, in addition to their other articles, and the result had been permanent relief of their ailments. Bearing these facts in mind, I have, for some time past, treated chronic lung cases by exposing terebene and turpentine in the room, in flat shallow dishes. The results have been, as yet, satisfactory, but further trial is necessary before a definite conclusion can be drawn. I shall be obliged if any member of the Association can inform me whether any statistics have been made as to the health and immunity from lung diseases of residents of pine woods, vendors of, and workers in, paraffin and other volatile hydrocarbons; and also whether any experiments have been made by exposing any of the above substances in wards for consumption, or other sick chambers. If a curative action can be proved, it would be useful in indicating a site for a sanitarium for chest diseases.—*British Medical Journal*, May 29, 1886.

FREQUENCY OF DISEASE OF THE UTERINE APPENDAGES.—At the close of a paper on this subject Dr. H. C. COX, of New York, draws the following conclusions:

1. Ovarian disease is *not* as common as it has been

represented; the surgeons, and *not* the pathologists, being responsible for the prevalence of the contrary opinion.

2. Because an ovary is partially diseased, it does not follow either that its functions have been materially impaired, or that its removal is imperative.

3. The expressions "cirrhosis" and "cystic degeneration" commonly applied to the ovary are mischievous terms, which are too often used in justification of *unjustifiable* operations.

4. Actual disease of the tubes is far less frequent than is generally believed. Lesser degrees of inflammation, especially slight "catarrhal salpingitis," are seldom appreciable to the pathologist, still less to the surgeon.

5. Many of the symptoms ascribed to disease of the uterine appendages are really due to *localised peritonitis*, and will *not* be removed by a removal of the appendages.

6. The physiology of the ovaries and tubes is still imperfectly understood; their pathology must then remain *sub judice*, and operations for their removal, on the ground of limited disease alone, must be regarded as largely empirical. To which I would venture to add the prediction:

7. The present enthusiasm in this country in favor of Tait's operation will not endure, because it will eventually be discovered that the number of *permanent* cures is entirely out of proportion to the number of operations.—*Am. Jour. of Obstetrics*, June, 1886.

"HOT EYE" IN ASSOCIATION WITH GOUT.—MR. JONATHAN HUTCHINSON, in a note on this subject, says: The following item of evidence is, I think, valuable reference to the connection of certain diseases of the eye with gout. A gentleman, named W., consulted me on account of attacks of irritability, first of one eye, and then of the other. The eye would become a little red, and feel as if he had sand in it. The attacks would usually last from two to four days, but they recurred very frequently, and were a source of much annoyance. He had made his own diagnosis before coming to me, and remarked, "I never knew what they meant until, a year ago, I had an attack of gout in the great toe." He was of dark complexion. He had, of late, been very careful in his habits, but he inherited gout strongly on both sides. Having noticed the identity of names, I asked him if he was a relative of a certain Dr. W. "Yes," he said, "I am his first cousin, and there is the same inheritance in both of us." In the latter case the patient, then a young man, lost one eye from recurrent attacks of iritis, and had much damage to the other. His case is given in the series which I have published, illustrating the peculiar form of destructive iritis which goes with hereditary gout. Thus the two cases support each other, and afford strong evidence: firstly, as to the connection, with inheritance of gout-tendencies, of the destructive form of iritis; and, secondly, with personal proclivity to gout of the "hot eye."—*Brit. Med. Jour.*, May 29, 1886.

SATURDAY, JULY 24, 1886.

HEPATIC PRESSURE AND THE CONDITION OF
THE RIGHT SIDE OF THE HEART.

In the *Lancet*, of May 15, DR. W. PASTEUR calls attention to a rather novel and apparently valuable method of estimating the condition of the right side of the heart. It has been known for some time that when, under certain conditions, pressure is made over the liver a distension of the superficial veins of the neck is seen. Dr. Pasteur has found that in cases which showed evidence of great over-distension or failing compensation in the right heart, there is a distension or over-filling of the external jugular veins, apparently from below, with or without pulsation or undulation, which takes place when pressure is exerted in the right hypochondriac or epigastric regions with the flat of the hand, the direction of pressure being backwards and upwards. The patient should be first placed in the recumbent posture, with the neck slightly extended and the head turned a little to one side, care being taken that the muscles of the neck are not in a state of tension. "The sign is usually best marked on the right side, but may in almost every case be demonstrated on the left side also. It is essential that the movements of respiration should be normally maintained throughout the examination."

Dr. Pasteur believes this sign to be invariably present in well-marked tricuspid incompetence, whether functional or due to disease of the valves. This he has had confirmed by four autopsies. And besides these cases there are a considerable number which ultimately recover, in which the sign is present at one time or another with varying intensity. "Such are instances of mitral valvular disease, whether regurgitant or stenotic, and of chronic pul-

monary emphysema, complicated with acute or severe general bronchitis." Dr. Pasteur has frequently observed a partial filling in of the supraclavicular fossa when the pressure is first made, and this is especially marked in thin subjects. It may perhaps be accounted for to some extent by simple mechanical displacement; but he thinks it chiefly due to an involuntary arrest or modification of breathing, and almost always subsides in a few moments. Of course the amount of pressure required varies in different persons, and in some cases there may be such rigidity of the abdominal muscles that pressure cannot be made directly upon the liver. The pressure should be gradual and steady, as otherwise an attack of coughing may be induced. The manipulations should be discontinued on the occurrence of pain.

Should this sign be regarded as evidence of slight tricuspid incompetence, or simply of great over-distension of the right heart falling short of tricuspid failure? This is an important question, as these are the cases in which we must consider tricuspid incompetence from a prognostic point of view. "Venous pulsation is generally absent, and often the cervical veins are but slightly distended. Not infrequently there is undulation at the spot where the distension of the vein ceases. This may be systolic only, or double, and synchronous with the heart beats. The valves of the external jugular veins are usually competent, and the veins empty completely with each inspiration. The effect of pressure below the ribs varies in these cases with the amount of obstruction to the venous return. 1. In the least marked cases, the vein, although not perceptibly distending under the pressure, is seen, nevertheless, not to empty completely during inspiration. 2. In others a degree more severe, a moderate distension results; the vein becomes visible as far as the anterior border of the sterno-mastoid muscle, more rarely as high as the angle of the jaw. At the same time the spot where the undulation was visible becomes shifted higher up the vein, and the character of the undulation is not infrequently modified, the double variety being replaced by a simple systolic flicker, the single variety usually disappearing altogether. 3. In cases yet more severe, but in which the usual signs of tricuspid regurgitation are not developed, the pressure sign is often elicited with great distinctness, with or without undulation, and is, I think, here to be regarded as indicating early tricuspid failure." In the second class of cases, differing from the third in degree only, Dr. Pasteur is inclined to think there is great overdistension of the right heart, possibly with excessive strain on the valve-cusps, but falling short of regurgitation.

What is the mechanism of the production of this phenomenon? Undoubtedly it is complex. Dr. Pasteur suggests the following factors as entering into it: 1. Compression of the inferior vena cava by the liver, especially in cases in which the liver is enlarged. It is not necessary that the liver should be enlarged, but this compression of the vena cava by the liver probably acquires more importance in cases of tricuspid regurgitation with pulsating liver. 2. The second factor is probably a lessening of the inspiratory action of the thorax from interference with the movements of the diaphragm; and Dr. Pasteur thinks this a more important factor. "It may be urged against it that, if true, pressure below the ribs should produce the same effect in healthy individuals. But I think it may be fairly argued that, whereas in health the heart and lungs may, and do almost immediately, adapt themselves to slight modifications of pressure, etc., within the thorax, it does not follow that in disease they possess the same capacity." 3. Direct mechanical interference with the proper movements of the right side of the heart is probably the third factor, and will be readily understood when we recall the anatomical relations of the right auricle and ventricle to the diaphragm and liver.

The absence of this sign may be a valuable diagnostic guide. Dr. Pasteur reports a case in which there were symptoms of severe bronchitis and emphysema, the external jugular veins being distended and filling rapidly from below, but not pulsating visibly. Examination of the chest showed nothing beyond marked emphysema and somewhat increased resistance, without dulness, and slight bronchitis of the larger tubes. Firm pressure below the ribs produced no change in the external jugular veins, and there was no clear evidence of obstruction of veins within the thorax. On this evidence a diagnosis of intra-thoracic growth obstructing the superior vena cava was made, and the diagnosis was confirmed by the autopsy.

CREMATION.

"A HASTY ENDORSEMENT.—At the last meeting of the American Medical Association the following resolution was adopted by a majority of 159 to 106: 'Resolved, That cremation or incineration of the dead has become a sanitary necessity in populous cities, and that this Association advises its adoption.' This is an example of the hasty and careless action which too often characterizes our societies. While cremation is an excellent thing for those who like it, it has not yet been demonstrated that it is 'a sanitary necessity in populous cities.' The cremationists have

not yet been able to trace a disease, much less an epidemic, to the suburban graveyards of our populous cities. We have always commended the practice of cremation as an advance in sanitation, but it is too soon to call it a necessity."—*The Medical Record*, July 17, 1886, p. 72.

We have copied the above paragraph entire from a recent number of *The Medical Record* for the purpose of correcting the erroneous impression it conveys concerning the action of the Association on the subject of cremation at its last meeting. The official record of the proceedings shows that on the third day of the meeting of the Association Dr. J. M. Keller made a report on cremation which closed with the resolution quoted by the *Medical Record*. A motion to lay it on the table was negatived. Then, under a call for the previous question cutting off discussion, the resolution was adopted by a vote of 159 to 106, as stated in the *Record*. But a motion was immediately made to reconsider that action which was carried by a vote of 198 to 70. Then, on motion of Dr. John Morris, of Baltimore, both the report of Dr. Keller and the resolution appended were referred to the Section on State Medicine. The following day the Section on State Medicine reported to the general session of the Association the following resolution, which was adopted: "Resolved, That a Committee of this Section be appointed to *further consider* the subject of cremation, with instructions to report their conclusions to the Section at the next annual meeting of the Association." The President appointed Drs. J. M. Keller, of Hot Springs, Ark., John Morris, Baltimore, Md., F. Formento and Samuel Logan, of New Orleans, La., and G. S. Franklin, of Ohio, on the Committee.

It is thus evident that instead of "A Hasty Endorsement," the American Medical Association is likely to take quite as much time for the consideration of cremation as the most conservative could ask for.

A STUDY OF THE SENILE TESTICLE.

In the May, 1886, number of the *Annales des Maladies des Génito-Urinaires* is an article under the above title, by H. G. ARTHAND, in which the following conclusions are drawn: "1. At about the age of 50 years the human testicle is subject to a gradual regression which induces atrophy. 2. This atrophy is characterized by a marked pericanicular sclerosis and by the disappearance of the epithelial element. 3. As a result of the sclerosis there appear atrophy of the seminiferous tubules, varicose dilatation of the ducts of the epididyma, and later the formation

of cystic cavities. 4. The sclerosis and its accessory phenomena may be regarded as the result of vascular lesions and of the insufficient nutrition of the seminal glands in advanced age."

It would be interesting to know where M. Arthand obtained the specimens from which such extraordinary conclusions were drawn. To take the conclusions seriatim, we are informed that at about the age of 50 years the testicle is "subject to a gradual regression which induces atrophy." We are not informed as to the time at which the atrophy appears after the beginning of this gradual regression, though it would be supposed that it follows at an early date after the age of 50 years. Are we then to draw the (legitimate) conclusion that a man who marries at or after the age of 50 years may not reasonably expect children? This conclusion is certainly legitimate from the premise; but is as certainly untrue. That the inference drawn does follow is shown by the second conclusion, that "this atrophy is characterized by a marked pericanicular sclerosis and by the disappearance of the epithelial element;" and by the third conclusion.

It is impossible to believe that M. Arthand could have examined the organs of healthy men; or if he did we can only conclude that M. Arthand's countrymen decay at an earlier age than men of other nations. For an atrophied testicle, and one characterized by sclerosis and loss of epithelial element, certainly cannot be of much if of any service. Furthermore, the loss of virile power must begin before the age of 50 years, since we are told that "the sclerosis and its accessory phenomena may be regarded as the result of vascular lesions and of the insufficient nutrition of the seminal glands in *advanced age*." If this be true the decay must begin some time before the age of 50 years, as it cannot be supposed that a previously healthy organ can take on lesions, which are the rule and not the exception, which will cause its decay in a few months. These vascular lesions and insufficient nutrition of the seminal glands (by which term we are to understand *testicles*) occur in *advanced age*, we are told, and cause the sclerosis and atrophy which appear at about the age of 50 years. We cannot believe that M. Arthand's countrymen are in *advanced age*, or in a state of senile decay at, and even before, the age of 50 years; and certainly men of other nations are not.

THE CURATIVE POWERS OF ERYSIPELAS.

Fehleisen, we believe, was the first to inoculate erysipelas for the purpose of curing certain forms of skin disease, and since that time various facts have

been adduced to show that this affection has an undoubtedly curative effect on certain tumors and affections of the skin.

BIEDERT has recently (*Deutsche Medicinal Zeitung*, No. 5, 1886) described a case of sarcomatous tumor of the mouth, in the case of a little girl, for which he was not permitted to operate, and which was successfully removed by the inoculation of erysipelas. The sarcoma occupied the left tonsil, and was about as large as a hen's egg when he first saw it. Twenty months later the tumor had invaded the whole posterior portion of the mouth and the anterior portion of the throat, the anterior portion of the floor of the mouth, principally the left half of the tongue, and protruded between the lips as an ulcerated mass. It had also grown into the nasal fossæ and attacked the skeleton of the face, and on the right side the eye was partly closed by a mass of exuberant tissue. On account of the foetid discharge from the mass great care was taken to place the patient away from the others; and it seems that so much care was used that she was placed in a bed which had been a short time previously used by a patient with erysipelas. Three days afterwards she was attacked with this affection, more especially on the exposed ulcerated portion of the face. Though the temperature rose to a great height, Biedert did not interfere in the least with the intercurrent affection, hoping that it would have a salutary influence on the sarcomatous tumor. In the six days of the erysipelatos fever the sarcomatous mass melted to an astonishing extent. Suffice it to say that on the sixteenth day after the development of the erysipelas the tumor had entirely disappeared except a nodule on the tongue, and one in the cicatrix at the ala of the nose, which were removed. It may be added that tracheotomy was performed when she was admitted to the hospital.

WHAT CONSTITUTES A CONSULTATION.

"TO THE EDITOR OF THE JOURNAL: I submit a hypothetical case and several questions for your consideration. As a favor please answer.

"A man requested a regular physician to visit his wife, who was supposed to be in a critical condition, having been delivered a few hours previously (same day) under the care of a homœopathic physician. The physician responded to the call, examined the patient, and gleaned the history of the case from friends, and the homœopathic physician who was present. A prescription (not discussed) was left by the regular physician who retired and saw the patient no more.

"1. Was this a consultation in the true meaning of the term?

"2. Did the physician violate the code, especially Article IV, Section 1?"

PHYSICIAN."

July 10, 1886.

Answer.—Regarding the hypothetical statement above as strictly correct, we answer both questions in the negative. To visit a patient represented to be in great distress or critically sick, examine the patient and get whatever information can be obtained from those present, even if one of them happens to be a physician, either regular or irregular, and then proceed to administer whatever relief can be afforded, whether it be to introduce a catheter, apply the obstetric forceps, or write a prescription and give the necessary directions for its use to the patient or those nursing him or her, constitutes no more a *consultation* with the physician present in the room than with the nurse or any other party present.

If, however, the physician thus called in a presumed emergency, not only examines the patient and gets all the needed information he can, but also then turns to the doctor present and enters into discussion with him concerning the nature of the case, and its proper treatment, it constitutes an actual consultation with him. See JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Vol. IV, page 537.

THE NEW WORK ON RENAL DISEASES, by Dr. Purdy, mentioned in a recent editorial in THE JOURNAL, is published by Lea Brothers & Co., Philadelphia, and can probably be found in the medical book-stores generally.

EPIDEMIC CHOLERA continues to prevail in some parts of Italy, and is extending moderately to the north. But the summer is already so far advanced that there is very little danger of it invading Germany, France or the British Isles, and still less of its reaching this country the present year.

SOCIETY PROCEEDINGS.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Semi-Annual Conversational Meeting, April 22, 1886.

THE VICE-PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

W. E. HUGHES, M.D., RECORDER.

DR. GEORGE A. PIERSOL read by request a paper on

MEDICAL PHOTOGRAPHY.

The character of photographic work which the medical man may probably desire to undertake may be divided into three groups: 1, photographing

specimens; 2, photographing patients; 3, photographing microscopical specimens; to which, possibly, a fourth should be added—making lantern slides or enlargements for the purpose of illustrating lectures. As to outfit, all of these requirements must be borne in mind. At the present time, possibly the best equipment for medical work would be one of Walmsley's modified copying cameras, as manufactured by the American Optical Company, taking a $4\frac{1}{4} \times 5\frac{1}{2}$ plate fitted with a first-class lens. Regarding the latter, those desiring the best might limit their choice with advantage to the lenses made by Ross, Dallmeyer or Beck. Personal experience with the Beck lens warrants a most favorable recommendation, as its superior qualities adapt it admirably for work requiring fine definition with great focal depth. As a matter of economy the excellent lenses of Daclot might be substituted for the higher priced English glasses. As much less expensive the "Waterbury" outfit (camera, lens and tripod costing but \$14) is worthy to be considered. The addition, however, of a light wooden extension is imperative to obtain sufficient length of bellows to reproduce specimens of a normal size—a matter often desirable. A lens adapted for medical work would be a rapid rectilinear combination of about $8\frac{1}{2}$ or 9-inch equivalent focus—a shorter focus lens possessing insufficient focal depth. In addition to the camera and lens, a simple dark room outfit, embracing non-actinic lantern, three trays, graduate, dust brush, light-proof box for opened packages of plates, and a few tubes, is necessary. Proper illumination is essential for satisfactory results. An evenly distributed top light is most desirable. This can be obtained readily from a skylight; such a convenience, however, is frequently wanting. An excellent substitute may be readily had by running the apparatus to the open air and stretching over all a piece of muslin, thus providing a mellow, evenly distributed top-light admirably adapted for photographing specimens. In focussing the use of a focussing glass is advantageous. Focus without the diaphragm on a point lying midway between the extremes of the planes of the specimen; afterwards put in the smallest stop (say No. 128 F., = 45.2 English scale). The small stop necessitates a rapid plate unless the exposure is unduly prolonged. A fast plate and small stop, when properly employed, yield pictures with the best possible definition and great focal depth, qualities very essential to satisfactory representations of specimens.

In order to insure acceptable results a correct exposure should always be attempted. The length of exposure depends upon many conditions—among others, actinic power of the light, this being modified by sunshine or clouds, by time of day, by season of the year; color of the specimen—a tissue deeply dyed with blood requiring much greater exposure than the alcohol bleached organ; character of the sun; size of diaphragm; sensitiveness of the plate; strength of the developer. Since these all modify the duration of any individual exposure, the oft heard comparison as to the bare numbers of seconds given upon various negatives are of very little importance. Each worker must determine for his own conditions

the exact number of seconds required on the ordinary specimens, and with this as a basis meet changing conditions as the occasion demands. While there are many excellent formulæ, the following developer has always answered admirably, and with it, by slight modifications, all kinds of work may be satisfactorily performed:

No. 1.

B. Pyrogallie acid (Schering's).....	1 oz.
Sodium sulphite.....	6 oz.
Water.....	48 f3.

No. 2.

B. Sodium carbonate.....	4 oz.
Water.....	48 f3.

No. 3.

B. Sodium bromide.....	1 3.
Water.....	1 3.

Use equal parts of No. 1 and No. 2 with 3 to 5 drops of No. 3 as a normal developer, the entire bulk of the developer being say 3 f3. Remember No. 2 accelerates, while No. 3 retards development; No. 1 giving density. A plate is fully developed when the deep shadows show some detail and when the cardinal outlines of the picture show on the back of the plate with reflected light. The most usual failures result from over-exposure and under-development. When a plate blackens rapidly, without the requisite amount of contrast between the high lights and deep shadows being at first present, we may strongly suspect over-exposure. Pour off the developer, flood with water, and then proceed once more with a developer to which say 20 or 30 drops of No. 3 have been added.

The remedy for under-development is evident. Strongly to be emphasized—select a good brand of plate, choose a reliable developer, and only change when there exists a strong reason for so doing; by this plan alone can the peculiarities and valuable qualities of any plate be learned. In addition to these fixed conditions, by at first employing but one lens and a single diaphragm, the path of the tyro is greatly smoothed. In photographing a patient, if possible a skylight should be used; when, however, none exists we can succeed fairly in any well lighted room, preferably one having two side windows. Opposite to window No. 1, and about four feet removed, we place our subject almost parallel, facing the second window. The lower half of window No. 1 is covered with muslin, while over the upper half is partly drawn the shade. Window No. 2 (further removed from the patient, but toward which he looks) is unobstructed. The camera is placed somewhere near the second window. Some simple background should be improvised and the darker side of the subject should be lighted up by a reflector of white muslin. Since the actinic power of light is immensely reduced within doors, our exposure would be unduly prolonged if we used the smaller diaphragms; we are therefore usually compelled to use the larger ones—Nos. 8 or 16. Photographing microscopical specimens requires a camera with a long bellows, 24 to 26 inches. This may be had by adapting to the front of an ordinary camera an extension, which may be readily constructed of wood, cardboard or tin: The

inner surface of the entire track of the light from the objective should be lined with black paper with matt surface. Any microscope admitting of a horizontally placed tube, with a good stage and centering sub-stage, may be employed. Likewise any objective possessing good definition and flat field may be used. The eye piece is best removed, the camera and microscope being united by simply inserting the draw tube into the extension of the camera and wrapping the joint with a few pieces of some black fabric.

Illumination is very important. Four sources may be considered—lamp, calcium, electric and sunlight. Calcium and the electric lights, while quite satisfactory by way of experiment, are practically debarred by the expense and inconvenience attending their use. The incandescent electric light, at the present time, offers little advantage over good lamplight, and is far inferior to sunlight. It may be stated once for all, that sunlight properly employed is the best possible illuminator for photomicrography. As it requires some care in its employment, and, above all, the devotion of the busiest hours of the day, we may inquire what can really be accomplished by lamplight. Mature consideration and considerable experience justify us in saying that with care and proper manipulation really good photographs may be made with powers up to the $\frac{1}{6}$; of course very much higher lenses may be employed—even the $\frac{1}{4}$ and $\frac{1}{8}$ —but thoroughly satisfactory lamplight work with lenses approximating 1,000 diam. is seldom if ever seen. One thing seems demonstrated beyond question: that with any power it is almost impossible to obtain the soft but brilliant micronegative, full of detail and vigor, that sunlight is capable of yielding. For lamp light a lamp with a single moderately broad wick should be employed, the edge of the flame being turned toward the object. For very low powers, 3—1 $\frac{1}{2}$ inch, no condensing lens is necessary. With higher powers, the interposition of a 4-inch focus plano-convex lens is advantageous, and with still higher lenses (say from the $\frac{3}{8}$ up) some form of sub-stage condenser in addition is almost imperative. After many experiments with various forms, a "B" eye-piece as a condenser seems to yield the best results, giving a powerful and evenly distributed illumination. Accurate centering and even distribution are of the utmost importance. First centre the sub-stage condenser. Avoid "pushing" the illumination, as when the condenser is racked too high the margin of the field is destroyed. Experience teaches the advisability of using a slow "clean working" plate (say Carbutt's "B.") in preference to the very rapid brands. A mirror placed at the end of the work table opposite the ground glass of the camera, is of great assistance in adjusting illumination; a small hand glass is also convenient to reflect the picture when hunting fields. The most important, as well as difficult, manipulation is focussing. With a short "pull" there are no special requirements, but when a long camera is extended, removing ground glass to three or four feet, some arrangement of moving adjustment is necessary. The simple arrangement with cord and weights, which we devised eight years ago, and which has of late become extensively used, we still

recommend as meeting all possible requirements. It has been put to the severest tests with powers of over 3,000 diam., and never has been found wanting either in delicacy or accuracy. A modification may be applied to the coarse adjustment.

A focussing glass is indispensable; the point of most accurate focus is where the image seems to melt into the ground glass. Preparations must be well differentiated and thin, possessing sufficient contrast and actinic opacity. In certain cases, by using glass of a complementary color to the stain, excellent results are obtained. While lamplight suffices for low powers, yet for the high powers or for difficult work, sunlight by all odds is to be preferred. By arranging a simple mirror to swing laterally and vertically, we can substitute the necessity for a heliostat. Light from this mirror passes through a plano-convex lens of 8 inches focus, through a cell of ammonia and sulphate of copper, to the substage condenser. Here, again, accurate centering and evenly distributed illumination are absolutely essential for good results. To those aspiring to the best results, especially with difficult subjects and high powers, a trial of sunlight is strongly urged, as by this illumination alone are many of the capabilities of photomicrography rendered possible.

Succeeding his address the lecturer exhibited on the screen about fifty examples of various kinds of work. Nearly half of these were photographs of pathological specimens; the remainder were photomicrographs of histological and pathological preparations, taken with objectives giving from the lowest to the highest amplifications, among which an admirable photograph of the bacillus tuberculosis attracted much attention.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, May 6, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

DR. HOWARD A. KELLY read a paper on

ASEPSIS NOT ANTISEPSIS; A PLEA FOR PRINCIPLES, NOT PARAPHERNALIA, IN LAPAROTOMY.

Medicine, like other branches of science, has been most retarded in its growth by the accumulation of all sorts of useless details. Some of these incrustations still clog the advance of abdominal surgery, and will be given up with a notable diminution in the general percentage of mortality. I refer to the use of carbolic acid and mercuric solutions at the operating table, and to the continued use of any elaborate abdominal dressing.

The use of antiseptics in the patient's belly is full of danger and inconsistencies, for the following reasons: 1st. If used in strength sufficient to certainly prevent sepsis, the patient is very often killed along with the germs. I have myself seen death from carbolic acid poisoning. The *American Practitioner*, November, 1881 (p. 261), quoted by Dr. Goodell: "The first four cases done in the theatre at the beginning of last session had hæmorrhage from the kidneys and two of them died. I never had anything

like that before. It was purely carbolic acid poisoning; of that I have no doubt whatever." Thomas Keith speaks of several cases in his own practice, and references might be indefinitely multiplied. Regarding the use of bichloride solution, it is sufficient to say that its use has been very much curtailed in all maternity hospitals even as a vaginal wash. The line is here a very broad one, for the limit appears only to depend upon the most variable of all factors, the individual susceptibility.

2d. It is the great tendency of all operators, and in particular their assistants, to forget the principle involved, and pin their faith to the accidental means of establishing it. This can be seen abundantly illustrated in almost any hospital in the land, where a clean napkin worked around the joints and grooves of the instruments in use, or carried under the nails of the operator's fingers, will exhibit sad evidences of soil. Then, too, the actual conduct of the operator is often modified by the false sense of security begotten by the incomplete use of antiseptics. I saw this well illustrated by a surgeon of more than local repute. The case was a herniotomy, in which a large femoral sac was opened. The spray was throwing out a dense cloud, instruments and sponges were immersed in a two per cent. solution of carbolic acid, and elaborate dressings were ready. A coil of intestine protruded from the wound for several inches, and it lay, first, on the old hospital blanket below, and then, in the effort to reach the ring, was turned upon the night-gown above. The antiseptics were here made a farce by these and other glaring inconsistencies.

If germicides must be used at all, let it be before the operation, and in strength sufficient to neutralize any sepsis about instruments, sponges, etc. Then let the operator go to work with clean instruments, clean sponges and clean hands, and he will need no antiseptic, and the patient's belly will no longer be a battle-field where germs and solutions fight, often with such direful results to the host. It is my belief that it will not be long before the day of solutions will be past, and that in the future the successful surgeon will go to his work with pure water or dry pans for his instruments, and fluid enough to cleanse sponges. My own practice has been to use hydrant water boiled for an hour and allowed to stand, or better still, distilled water, as used by Prof. Schroeder, and independently suggested and used by my friend, Dr. Joseph Price. I do not believe that reservoir water, dirty as it often is, ever contains any of the specific matter productive of septicæmia; but the process of boiling and using only the supernatant liquid makes it perfectly harmless.

Another fallacy discarded by some of the greatest operators but perpetuated by many, is the transference of the use of the elaborate Listerian dressings of general surgery to the abdominal wound. These dressings, so manifold and multiform, are clearly intended to prevent sepsis from penetrating the now closed abdominal wound. This is an accident which fortunately never occurs in the intra-peritoneal method. The rapid agglutination of peritoneal surfaces effectively closes the sac. A sterile dry pow-

der will absorb the slight serous discharge at the edge of the wound and suture exits, and above this some absorbent cotton and a firm bandage is all that is required.

While the danger of infection of the peritoneum through the closed wound is nominal, that of an infection of the belly wall through stitch holes is very great, and this is best prevented by the dressing recommended by Keith, of carbolic acid and glycerine, one to eight parts.

With the mind thus freed from the notion that these solutions and dressings are accomplishing anything—from two such dangerous fallacies—operators at large will then work with a living consciousness of the real conditions of success, and they will then be on the alert from the beginning of the operation to its close, keeping within the mental horizon an exact knowledge of everything coming into contact with the patient's belly.

The expression of my convictions and practice will be of value in so far as they are in accord with the following letters upon the subject by the two greatest abdominal surgeons in the world, Lawson Tait and Thomas Keith. Lawson Tait, in a letter dated March 15, 1886, to the writer, says: "I still use tap water, and nothing else; it is never boiled. My instruments are prepared by being washed in soap and water merely. I use no elaborate dressings for the wound, never using anything at all except absorbent cotton wool. Yours very truly,

LAWSON TAIT."

From a communication from Thomas Keith, of Edinburgh, written March 18, 1886, I make the following extract: "The secret in abdominal surgery, the secret in all surgery, consists in carrying out the antiseptic principle. You may do this in a simple way or you may do it in a complicated way. All instruments, needles, forceps, sponges, etc., everything about the wound, must be disinfected. A weak carbolic solution applied to the wound can do no good, nor harm. You may safely use hot water. My instruments, after an operation, are scrubbed with a nail brush, especially the forceps points. This is repeated before the next operation with a five per cent. solution of carbolic acid. The greatest risk is that we put in septic matter on our hands, instruments, and sponges. Sepsis may come from the wound, but it rarely ever penetrates inside. I use a simple dressing of gauze, eight or ten folds, soaked in one to eight carbolic acid and glycerine, extending two or three inches or so beyond the line of incision on all sides. Over this some ordinary cotton wool, a flannel bandage, and nothing else. Use this and you will never use anything else. And don't look at it for a week or ten days. You ought, for the patient's comfort, to put on an antiseptic dressing of some kind. You will probably often have suppuration with stitches if you do not. Yours sincerely,

THOMAS KEITH."

DR. MONTGOMERY felt great interest in Dr. Kelly's remarks, reinforced as they were by the letters from Tait and Keith. The antiseptic method of treatment has done a great work for surgery, and the successive steps of listerism and cleanliness have

brought it up to the comparative certainty of result now attainable. We can now eliminate almost entirely the antiseptic agents, carbolic acid, mercuric chloride, thymol, etc., and can do as well by the most rigid attention to cleanliness in all details of hands, instruments, sponges, and the skin of the patient. Some years ago he felt gratified that, in a patient upon whom he operated before a class at the Philadelphia Hospital, with listerism and the carbolic spray, the temperature did not rise above 102°. Now, in his private hospital, with rigid attention to cleanliness and thorough washing of the peritoneal cavity with hot water, the highest temperature will be below 100°. After operations involving the opening of the peritoneal cavity, if there has been any opportunity for the escape into it of blood, pus, or cyst contents, he washes it out thoroughly with hot water. After closing the wound he closes it with sublimated gauze and absorbent cotton, and secures this with strips of plaster and a bandage. This dressing remains a week without need of disturbance. If gut sutures, or silk rendered aseptic by a coating of wax with carbolic or salicylic acid, be used, there will be no trouble about suture abscesses. In a recent case, in which the abdominal walls were two inches thick from adipose deposits, these precautions were observed and there was not the slightest suture trouble. He does not now consider the spray of any value; because we cannot use carbolic acid solutions strong enough to certainly destroy germs without poisoning the patient, and the spray only washes the germs down into the wound.

DR. CHARLES HERMAN THOMAS remarked that the experiments of Dr. Sternberg, of the Johns Hopkins University, a careful and conscientious observer, have developed the fact that some of the antiseptic solutions in common use, three per cent. carbolic acid, for instance, actually stimulated the growth of bacteria. Perfect cleanliness is the essential point, the foundation of surgical success. He has seen Dr. Kelly operate without disinfectants, his instruments being placed in a dry pan, and his results prove the truth of the assertions he has made this evening.

DR. M. PRICE had experienced great difficulty in his attempts to secure absolute cleanliness. He has seen half a dozen unclean hands introduced into a peritoneal cavity during operation, simply from curiosity; sponges picked up from the floor, napkins from a dusty window-sill, instruments from a soiled blanket, and each used on peritoneal or absorbent surfaces; sponges that have been filled with pus used again in the peritoneal cavity, and in general, extreme thoughtlessness in the little details of cleanliness that compelled the full power of antiseptics to bring good results. He has had good results in pyosalpinx even where purulent cysts have burst in the abdominal cavity, but he allows only the operator's hands to enter that cavity, and practices the most thorough washing out with clean water. He has been burned by simply holding a carbolic ligature in his mouth for a few minutes, and feels sure that the retention of a number of such ligatures in the abdomen would be quite likely to give rise to trouble.

DR. CHAS. MEIGS WILSON said that cleanliness, by

whatever means obtained, is the great element of success in abdominal surgery. As absolute cleanliness can best be obtained by the use of agents possessing germicidal and anti-putrefactive properties in the preparation of the atmosphere, the operator's person, the instruments, sponges and dressings, it seems to be the part of wisdom to employ such agents up to the time of and even during the operation. With a perfectly clean room and furniture, clean air, clean instruments, and clean hands, possibly no antiseptic agent would be needed. But unfortunately, such conditions do not universally or generally exist, and to attain them we must resort to the use of some efficient antiseptic. Care should be taken to employ some agent which is efficient and at the same time non-poisonous. In English and Continental hospitals, where excessive antiseptic precautions are employed, the success attained compared with the previous mortality rate proves unquestionably the great value of such precautions. The united testimony of experienced American operators as to the value of antiseptic precautions should not be set aside. I believe that all instruments should be submitted to the purifying influence of dry or moist heat. That the towels, sponges and dressings should be left for twenty-four hours in a boiling hot solution of mercuric chloride 1 to 2000, and that the silkworm-gut or fine wire sutures and ligatures should be kept in a very weak solution of carbolyzed oil. To my mind the terms antiseptic and aseptic are synonymous. My own experience has taught me that the best and least dangerous antiseptic agents are those which prevent or retard putrefactive changes, rather than the more dangerous class of agents which possess decided germicidal powers.

DR. PARISH said that antiseptics are not intended to take the place of cleanliness. The greater the care bestowed on cleanliness in all details the less will be the need for antiseptics. Boiled water, filtered, is a good washing material; patient hands and instruments must be clean to insure good results. Absorbent lint, wet at time of using with a 1 to 2000 mercuric chloride solution is a good external dressing. Dr. Parish agreed with most of Dr. Kelly's statements, but he believes in the value of antiseptic vaginal injections after labor in hospitals. The maternity wards of the Philadelphia Hospital showed a large number of deaths, varying from three to ten per cent. for many years prior to 1885; but last year, in 247 cases of labor there were but two deaths. One of these was after Cæsarean section in a patient who had been in labor nearly three days before she was brought into the hospital. The other fatal case was in an idiot, and was largely from other causes than the labor, which was not at fault. These good results are due to the use of mercuric chloride injections principally, although we have now new wards and opportunity for frequent change of nurses where advisable. In a case of septicæmia following adherent placenta, the patient seemed almost moribund, but hot uterine injections of mercuric chloride, 1 to 4000, stimulated her and led to recovery. Water is boiled to destroy possible germs, and filtered to get rid of various impurities not held in solution.

DR. M. PRICE thought the heat of the injection used by Dr. Parish was the most important element in stimulating the patient; but the mercuric chloride would do no harm, and the fact that improvement commenced and continued from that time is the important point. The reaction against the use of antiseptics should not be allowed to go too far. They have done great good and can not be discarded.

DR. SOPER, formerly of the Rotunda, Dublin, upon invitation from the President, remarked that this was a very mixed question. That neither cleanliness nor antiseptics could be dispensed with. He has seen cases do well under all conditions without antiseptic precautions, and if the solutions are dangerous we must be cautious in their use. He believes thoroughly in cleanliness, and would use antiseptics when he thought them needed. It does not do to run into extremes.

DR. KELLY replied, in closing the discussion, that he was both surprised and gratified that so many members of the Society had expressed their approval of his paper. In two or three instances, however, he had been grievously misunderstood. He believes it to be the great glory and the crowning triumph of *antiseptics* to have discovered *asepsis*. He had nothing whatever in common with those surgeons who claim that antiseptics have done nothing. The peritoneum is a vast, exquisitely sensitive "culture" sac. In the old time chance decided whether the uncleansed hand of the surgeon carried in suitable germs to multiply in the medium, and the chances were greatly against the patient. Now the use of antiseptics accidentally involves rinsings and cleansings which make the surgeon a clean man in spite of himself; and the patient generally escapes. In a more advanced position, and the one in which the surgeon is living up to a *principle*, the utmost precautions are taken by a preliminary use of antiseptics in sufficient strength, and he goes to his operation needing no germicides.

Let the battle-field be without the patient's belly and the germicide will there be sure of the victory every time. Statistics from foreign nationalities as quoted, instead of proving against, are one of the strongest arguments for, this position, for there the use of the germ-destroying agent is wholly *without* the patient's body.

(To be concluded.)

CHICAGO GYNÆCOLOGICAL SOCIETY.

*Forty-Sixth Regular Meeting, Friday Evening,
April 23, 1886.*

THE PRESIDENT, DANIEL T. NELSON, M.D.,
IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

DR. CHARLES CALDWELL read a paper entitled,

REPORT OF A CASE OF HERNIA OF THE UMBILICAL CORD.

I was called August 10, 1885, at 6 P.M., to attend Mrs. C., who was in labor with her ninth child. I made an examination and found a vertex presenta-

tion, first position; os well dilated but no bag of waters had formed.

The first stage of labor was completed at 7 P.M., and the second an hour later. The child, a female, was quite large with very broad shoulders, which were difficult to deliver. As soon as the child was expelled, I discovered she had a large umbilical hernia. I ligatured the cord and gave the child to the nurse, who removed it to another room, that the mother might not be alarmed at sight of the tumor.

The placenta was expelled by Crede's method and the uterus contracted firmly under pressure of the left hand.

After the binder was applied and the mother made comfortable, I examined the tumor more carefully. It was as large as a small orange and of similar shape. The circumference in the largest place—the centre—was about ten inches. The diameter of the orifice or abdominal opening, two inches. The sac was translucent and the viscera—intestines—could be distinctly seen when the child cried and forced them out. The umbilical vessels were on the left side of the sac. The skin was projected from the abdomen on to the side of the sac at its base about half an inch.

Diagnosis.—Hernia of the umbilical cord.

Pathology.—Ectopia of some or all of the abdominal viscera at the point of insertion of the umbilical cord, is usually due to an arrest of development of the abdominal parietes, and failure of the intestines originally projecting into the vitelline duct to return into the abdominal cavity. Simpson thinks it may sometimes be traced to peritonitis. Cleft abdominal walls, similar arrest of development to that of cleft sternum, may exist in the muscular structure of the front of the abdomen, which may expose the whole contents of the abdomen, or the central line of the abdomen may be weak from deficiency of muscular structure.

If the orifice is very small, it can be treated successfully by a simple compress and adhesive straps. But if large, nothing except a plastic operation is indicated.

The coverings of the hernial sac are, from without inwards (a) amnion, (b) peritoneum.

Treatment.—After examining the sac thoroughly I was convinced that nothing but surgical interference could save the child's life.

I called our President and Dr. Jaggard by telephone, but both were too busy to assist me that night. They both recommended a cork compress held in position by adhesive strips, evidently thinking it an ordinary case of umbilical hernia. I decided not to operate until the next day, and enveloped the sac with absorbent cotton, retaining it in place with a loose band.

The next afternoon, Drs. Dudley and Jaggard met me in consultation. After examining the little patient, they decided with me, that nothing but surgical interference would give her any chance of life, and kindly assisted me in the operation.

It was decided not to give an anæsthetic. Dr. Jaggard seizing the sac, gently forced its contents, the viscera, back into the abdominal cavity and I ligatured it as close to the abdomen as possible, but

did not draw the ligature perfectly tight. At the suggestion of Dr. Dudley the sac was now opened, to be sure no portion or loop of the bowel was confined by the ligature.

The peritoneum being opened, the index finger was passed into the abdominal cavity to hold back the bowel and protect it from the points of the hare-lip pins, which were passed at right angles to each other through the narrow piece of skin at the base of the sac. Two more ligatures, carbolized silk, were applied beneath the pins and were drawn tight enough to close the opening. The outer layer of the sac was trimmed off, leaving a stump one and one-half inches long. Dr. Dudley passed a gathering suture round the stump, sealing it more tightly. This completed the operation; after which the stump was dressed with iodoform—a narrow strip of carbolized gauze passed beneath the pins—several layers of absorbent cotton and a roller bandage. The child was restless that night, crying several times, but slept well the next day. I dressed the stump every day, reapplying a similar dressing. The bowels moved naturally until the 16th, when I discovered some fecal matter on the dressing as I removed it.

On the 17th, all the feces passed through the fistulous opening. The members of the family were very much alarmed and wished me to close the opening at once. I assured them that nature would close it without any further surgical interference. I called on Dr. C. T. Parkes for his advice. After hearing the history of the case he said it would undoubtedly close by granulation in a few days.

For four days all the feces passed by the fistulous opening, but on the fifth there was a little stain on the diaper. On the sixth more, and on the seventh all the feces passed *per rectum*.

The family were happy once more, for the fistula had closed. There were no symptoms of peritonitis at any time. Neither vomiting, tympanites nor pain. The patient did not cry more than babies generally do, but nursed and slept nicely, requiring no unusual care.

The bowel, at point of perforation, was held firmly bound to the abdominal walls by lymph, which was thrown out.

From this time the wound healed very rapidly. The end of the stump sloughed, leaving it quite short. The small intestine was probably the one perforated, for there was no odor to the discharges.

What caused the rupture of the bowel to take place I am unable to say. Probably, either a portion of the bowel was caught, and became strangulated by the ligature, or it was punctured by a pin, as that instrument was inserted.

Dr. Dudley says the surgical operation was certainly a laparotomy, for the abdominal cavity was opened and the index finger introduced.

DR. DE LASKIE MILLER said he had seen numerous cases of hernia, but thought this specimen was possibly more extreme than he had seen.

THE PRESIDENT asked Dr. Miller in how large a hernia he would deem operative procedure, of a plastic nature, necessary.

DR. MILLER did not think it possible to state, by

actual measurement; so much depends upon the condition of the tissues surrounding the opening, that the absolute diameter of the opening would not be the governing principle. If the borders of the opening are of considerable thickness and the tissues well developed, it would be possible to reduce and probably cure a hernia independently of any cutting operation. He inferred that in the case described in the paper, there was a deficiency of all the tissues except the peritoneum and the amnion, the skin projecting upon the sac one-half inch around the opening. He thought there was another explanation possible in this case, viz., that the duct leading from the umbilical vesicle remained or became patulous and the fæcal matter passed out through that; for the duct can be seen in the cord, even at delivery, in some cases. He inquired as to the cause of the arrest of development of the abdominal parietes in such a case.

DR. EDWARD WARREN SAWYER thought it not a very unusual thing to find a prolongation of the intestine into the cord. He once came very near tying the cord including a loop of intestine, so near that he had since observed the rule to always satisfy himself, by careful manipulation of the cord, that it contained no loop of intestine, and this routine practice had revealed the fact that very often a suspicious enlargement of the cord is found, sometimes extending three-fourths of an inch above the level of the abdominal wall, and the intestine, or portion of the omentum, is not infrequently projected into this cul de sac. He thought in the majority of cases nature would take care of the condition without any attention from the attendant. He had never seen so large a hernia as that described by Dr. Caldwell, and did not understand why it should have assumed a spherical shape; he could understand how it might be pyriform or sausage-shaped, and extend an inch or two into the cord, but how the cord could suddenly dilate and form a large globe, and this globe be followed with the contents of the abdomen, it was difficult to comprehend.

Dr. Sawyer inquired what there was about this case that enabled the physicians to decide so quickly that an operation must be resorted to in order to save the child's life. To him an operation would have been a second consideration. Dr. Jaggard evidently reduced the hernia without difficulty, and having reduced it, it seemed to Dr. Sawyer that a well applied bandage would have secured it. The operation was brilliant and creditable, but he thought an operation should have been considered, after the attendants had failed utterly to secure the hernia within the cavity by a well applied bandage.

It was stated in reply to questions that the child presented no symptoms; the hernia was reduced by Dr. Jaggard; the tumor about the size and shape of an orange; the operation was performed the day after birth; there was no evidence of strangulation of the gut.

Dr. Sawyer said that Dr. Caldwell had assured him that he was certain that in passing the hair-lip pins no part of the intestine was included, and the finger was introduced to push everything beyond the reach of the pin. Dr. Sawyer thought, however, that

the centrifugal pressure must have been considerable, and the contact quite severe. He thought it strange that none of the fæcal matter escaped into the peritoneal cavity, although there were adhesions between the intestine and abdominal parietes.

THE PRESIDENT: Of course every case must be decided on its merits, but might we not hope for the closure of the opening of an inch and a half in diameter, provided the tissues are well developed around it, without a cutting operation? It would seem possible to close as large an opening as in the case under discussion by simple adhesive strips. He had seen one case that reminded him of this; the opening was not as large, it did not exceed three-fourths of an inch in diameter, and the length of the sac was much longer than the opening. Into this sac there was projected a solid body. As the child afterward died, he found it was the *lobus Spigelii* of the liver. It was so conical, or heart-shaped, that the anatomy could not be made out until after death. The instruction to him in that case was the importance of not including any of the abdominal tissues by the ligature that might be passed around. He was careful to pass the ligature around the umbilical cord so as not to include the sac, but it might readily have been passed close to the abdomen and made to include the solid tissue, which, as he afterwards found, was a portion of the liver. The child died, not from the hernia, but from some want of development which he was unable to find out, no careful post mortem examination being allowed, but he believed there was lack of foetal development necessary to life. The child was fairly well developed, and seemed as if it should have lived, so far as this slight defect was concerned.

The PRESIDENT asked if any one could suggest the reason for the fæcal fistula. It seemed to him that in this case it was the result of inflammation caused either by pressure against the pins or the ligature; if the intestinal wall had been punctured by the pins, the physician would have seen evidence of it earlier.

DR. J. H. ETHERIDGE inquired whether this was not the youngest laparotomy on record. He wished to know if it would not be possible to crowd back the viscera and then hold them in place with adhesive strips.

DR. T. D. FITCH said that he had not had experience with congenital hernia at birth, but had seen it occur within twenty-four hours afterward, and had successfully closed an opening an inch or an inch and a quarter in diameter by the ordinary method, viz.: compress and bandage.

Dr. Fitch had had very peculiar success in the treatment of infantile umbilical hernia by the ordinary means, and he should hesitate very long about an operation until he had tried all the ordinary means. His method of treatment differed somewhat from the ordinary treatment, however, in the adoption of an elastic web bandage instead of the ordinary bandage or adhesive plaster, and he thought it far superior to an inelastic bandage, as it gave the child room for an accumulation of intestinal gases, which very often become painful when a fixed bandage is placed around

the abdomen. He first applied a hand compress, like a button-hole—(plano-convex)—to cover the opening. This should be large enough to extend three-eighths of an inch beyond the margin of the opening, and should be covered with one or two thicknesses of fine soft muslin. After returning the protruded substance *perfectly*, the compress should be fixed in position by short adhesive strips, then apply the elastic webbing around the body of the child tolerably tight, and let each turn of the bandage lap the previous one half its width, making a sufficient number of turns to cover six or eight inches of the abdominal surface vertically. He would leave this on, undisturbed, unless the child became restless, or exhibited some indication of injury, for a month or longer before removing it. He had never found that the skin suffered from the confinement of the perspiration.

Another advantage was that the elastic webbing being rough and the lips of the bandage holding each other, it always stayed in place, and held the button firmly and so secured the opening against any possibility of protrusion. He had used this method successfully for about thirty years. He had a case at Waukegan, which occurred twenty-four hours after birth; did not attend the mother at the birth, but was called to treat the hernia which was reducible, and would gurgle in and out at almost every respiration, bulging out as large as an English walnut. He visited the child only once, and told the parents to remove the bandage at the end of four weeks, when the opening was found entirely closed. The child is now 9 or 10 years old, perfectly healthy and always has been.

DR. CHARLES CALDWELL: The Fellows of the Society have evidently misunderstood the nature of the case described in the paper. I am sorry that such obscure and confused conceptions have been conveyed. The case was one of hernia of the umbilical cord, consisting in "the escape from the abdomen, at the point of insertion of the cord," of some of the foetal abdominal viscera, and was due either "to arrested embryonic development, preventing the complete closure of the abdominal cavity, or failure of the foetal intestines, originally situated outside the abdomen to enter the same" (Lusk). The remarks of most of the Fellows are accordingly irrelevant.

As no one who witnessed the operation was present at the discussion of my paper, several questions were unanswered.

Dr. Sawyer wished to know why we decided so quickly that surgical interference was necessary to save the child's life?

The consultation was held about twenty hours after the birth of the child, and at that time the outer layer of the sac, the amnion, was dark and gangrenous in several spots. Its nutrition was cut off when the cord with its umbilical vessels was ligatured, and it would have sloughed off in a few days, leaving the viscera covered by the peritoneum only. We were of the opinion that such a condition as then existed would be followed by general peritonitis and death without some surgical operation.

Dr. Byford wished to know the literature of the subject. He had been able to find but one case

similar to his. Thomas Bryant, in the last edition of his "Surgery," mentions the only case he ever saw and his treatment. In June, 1876, a child, one day old, was brought to him with hernia of the cord. The sac was translucent, the size of a small egg, and contained the cæcum and vermiform appendix. He pressed back the bowel with the thumb and forefinger, stitched up the cord at the umbilical orifice with deep sutures and ligatured the cord itself at the apex of the congenital hernial sac.

Recovery was complete without a single bad symptom. He recommends his operation in all similar cases, evidently considering it the only treatment indicated. So we were supported by the best of authority, in operating instead of trying to apply a compress. Should I ever meet with a similar case, I would perform an operation different from either Bryant's or mine.

I would first remove the amniotic layer of the sac, if it could be separated from the peritoneum, excising or amputating it at its junction with the skin, return the viscera and peritoneal sac to the abdominal cavity and close the abdominal opening as in a case of exploratory incision, or simple laparotomy. Either incising the peritoneal sac to better protect the bowels from needle points, or stitch to the bottom of the wound by deep sutures, and support the sutures by adhesive strips around the abdomen. I would recommend this operation after observing how quickly the amnion sloughed away. It might just as well be removed at once if it can be easily separated from the peritoneum.

(To be concluded.)

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

[We are permitted to publish, for the information of those intending to visit Europe, the following translation of a letter addressed by Dr. Cornil, of Paris, France, to Dr. E. W. Cushing, Hotel Pelham, Boston, Mass.—EDITOR.]

Dear Doctor:—Last year, in the month of July, you did me the honor of visiting me in my laboratory, Rue Lohmond. We discussed very earnestly the organization of private courses, rapidly made practicable and demonstrative, in which physicians, and especially American physicians, could learn in some months the technique of scientific specialties, such as normal histology, pathological histology, bacteriology, accouchements, ophthalmology, skin and syphilitic diseases, diagnosis, nervous diseases, autopsies. Now, I can tell you that we will organize these courses in union with some of my colleagues in the Faculty of Medicine, and that we will accomplish them with the Assistants and Fellows of the Faculty. For my own part I shall be happy to have them succeed, and that your compatriots may find in Paris, where we have so many resources, all the facilities of instruction that they receive at Vienna.

I am persuaded also that the American physicians and students will receive here a better welcome,

founded on all the sympathies which bind us to the American Nation, and on the desire to sustain the most friendly relations with your medical fraternity. My medical laboratory will contain, besides the necessary rooms for the practical work of the scholars, a hall for private courses in bacteriology, which will be presided over by M. Chaumesse. The courses in bacteriology will last six weeks, and sixteen scholars may pursue the course at a time, having at their disposition all the room and material necessary. This course will be very well organized. I have, besides, a hall for a practical course in pathological histology, which will receive about fifteen scholars, each one having his table at a window. This course will be given by M. Dr. Brault, and will also last six weeks. You probably know Dr. Brault, who has written, with me, a volume on the pathology of the kidneys. M. Brault is an excellent pathologist. M. Chaumesse is well informed on bacteriological technique, and has recently passed a month and a half at the Gesundheitsamt, in Berlin. In accouchements we have the course of M. Bar and M. Auvard, which is well given. M. Bar will give, besides, a more practical instruction in his hospital service, where he will admit some physicians and repeat operations. For nervous diseases M. Babruski, chief of the clinic of M. Charcot, will give some repetitions in the Hôpital de la Salpêtrière. For ophthalmology, one has yet only the puzzle of choosing. It is the same case with skin diseases and medical diagnosis. For this it will be very easy to have the lessons by series, with M. Capitan, chief of the clinique at Hôtel Dieu, or with another chief of medical clinic. For normal histology, there are just now demonstrative courses already prepared by M. Lattery. It will be possible to organize an analogous course if this does not suffice, either in the College de France or in my laboratory. As concerns autopsies, I make public autopsies at Hôtel Dieu, and I will let autopsies be made under my direction by persons who are registered. I will do this for all scholars, as the course is public.

You see that we are ready, and I assure you that your compatriots will find here all the means of instruction. To obtain information, they may address to my laboratory, which will be Rue de l'Ecole de Médecine, en Face de la Faculté (fronting the University) or to M. Chaumesse, or to another of my assistants.

Yours truly, DR. CORNIL,
19 Rue St. Gaillaume.

Paris, March 6, 1886.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The Fifth District Branch Meeting—Intussusception—Large Calculi; Operations for Stone—Epicystotomy for Sarcoma and Papilloma.

After Dr. Van Hoesenberg's paper, spoken of in my last letter, at the evening meeting of the Fifth District Branch of the New York State Medical Society at the Hotel Kaaterskill, the President, Dr. J. G.

Porteous, of Poughkeepsie, read the history of an interesting case of intussusception in which about seven inches of the intestines were discharged *per rectum*, and recovery followed without an operation.

Dr. C. R. Wood, of New York, said that it was the fashion now to operate in these cases, and the medical attendant who did not operate or send for a surgeon for that purpose was apt to be looked upon as actually criminal. At the Poughkeepsie meeting of the Fifth Branch he had read a case similar to that of Dr. Porteous, in which recovery also took place, although there was no operation; and such cases ought all to be published. Many lives, he thought, might be saved if this course was more frequently adopted. Laparotomy was very apt to prove fatal, and yet it was frequently resorted to even before other measures had been tried.

Dr. J. W. S. Gouley, of New York, said that he was fully in accord with Dr. Wood, if he rightly understood his views. "Belly cutting" had become such a mania among doctors that one was tempted to suggest that some of its advocates ought properly to be shut up in a lunatic asylum. More lives were lost than saved by laparotomy. While it was a perfectly legitimate operation, and of great service in its proper place, its scope and limitations were not as clearly understood as they ought to be. These limitations were, however, sufficiently well defined; and it was an undoubted fact that many cases recover spontaneously. Some years since he had collected quite a large number of these, and he remembered that in one instance six feet of intestine, and in another a still larger piece, were discharged.

So long as the intestinal canal remained pervious, operative interference was entirely uncalled for; but the moment that complete obstruction and commencing fæcal intoxication occurred, laparotomy should be performed. He believed that the operation was often performed after symptoms of peritonitis had set in, and that under these circumstances it was worse than useless. If the operation had any value at all in cases of this kind, it was when the symptoms of complete intestinal obstruction first showed themselves. Then, and then only should it be resorted to. Afterwards it would be too late.

Dr. John Shady, of New York, related the case of a lady who was kicked in the abdomen and died three weeks afterward. The autopsy showed the presence of peritonitis, with six inches of invaginated intestine. He mentioned the case, he said, to show the length of time that the condition might last.

Dr. Gouley exhibited a series of specimens of large calculi which had been removed by himself, and which he said he wished to serve as a text for some remarks upon what he conceived to be a safe method of ridding the bladder of these dangerous foreign bodies. There were fourteen or fifteen of these specimens, most of which had been removed by lithoclastic cystotomy; and Dr. Gouley gave a short history of each case; after which he went on to say that surgeons, like women, have their fashions. Too often the sentiment entertained was, "Perish the patient, but let me operate." The operation of lithotripsy and evacuation at a single sitting, the old pro-

cedure revived by Bigelow, at first sight seemed a very simple and easy affair; but the aspiration of calculous detritus as well as the preliminary operation of crushing, was in reality attended by great danger. He had seen two or three hours occupied in these procedures, and the result was very severe cystitis. This would be the consequence whenever any sitting at lithotripsy was prolonged. The operation, therefore, should be short. Yet one case of Bigelow's had lasted four hours, and during all this time the administration of ether was kept up. Even though the kidneys were diseased, the ether had to be gotten rid of through these organs, as well as by way of the lungs and skin; and acute nephritis from this cause had occasioned many deaths. But if nephritis was not caused, there was very liable to result permanent cystitis, which would inevitably shorten the patient's life. In many cases, therefore, cystotomy was far preferable to lithotripsy with aspiration. Two grand objects were accomplished by this procedure, as the patient was relieved, *first*, of prostatic obstruction; and, *second*, of the stone.

Still more recently an operation devised by Franko in the middle of the sixteenth century has been revived, viz.: supra-pubic lithotomy. Within the last eighteen months the operation had undergone what was considered a very important modification, consisting of the elevation of the bladder by means of a rubber bag introduced into the rectum and distended with water. This, however, was a delusive thing. The trouble was not want of space, as any good surgeon could remove the stone without difficulty. The real dangers were three: In the first place, there was a liability of rupture of the delicate peritoneum during a violent fit of coughing or vomiting. The first case in which the operation was done by a certain advocate of this method in New York was that of a child, and it was successful; but it was not to be forgotten that in children the bladder is in reality an abdominal organ. The second case was in an adult, and before the surgeon had left the hospital, after removing the stone, it was reported to him that the intestines were protruding through the wound. The operator believed that he had cut the perineum; but Dr. Gouley was of the opinion that the rupture had probably been spontaneous. The peritoneum was stitched to the abdominal walls, and the patient recovered; but if the accident had occurred at night, the intestine would no doubt have become strangulated, and death from peritonitis have resulted.

The second great danger was from extravasation of urine. Dr. Gouley predicted that for ten years the supra-pubic operation would be performed, and that when a sufficient number of deaths had resulted from it, it would be condemned and abandoned. Surgeons would, therefore, have to come back to lithoclasty, on account of its greater safety. The mortality in general in lithoclastic cystotomy was one death in eight cases, and in Dr. Gouley's hands the proportion was still smaller, one in eleven.

He then referred to epicystotomy for sarcoma or papilloma of the bladder. He had had several cases of the latter, and had operated in two of them; but both the patients died. If he were now called upon

to perform this operation in an otherwise healthy subject, he said he should be inclined to combine the two procedures; the infra-pubic operation for securing drainage, and the supra-pubic for the purpose of seizing and removing the tumor. This is the only condition in which he would admit the propriety of the supra-pubic operation.

Dr. Shrady said that he should like to ask Dr. Gouley whether he thought the use of certain kinds of drinking-water had anything to do with the causation of urinary calculi. It had been stated that stone had been much less frequent than formerly in New York since the introduction of the Croton water system. Again, it was found that in certain parts of the country it was much more common than in others. The late Dr. Dudley, of Kentucky, had performed an immense number of operations for stone.

Dr. Gouley said that his answer would be an affirmative one, although with a reservation. Potable waters containing such ingredients as limestone did not give rise of themselves to stone in the bladder. The impression formerly prevailed that certain potable waters would cause stone because the salts they contained would be deposited; but this was not the case. That brimstone waters were a prolific source of stone there could be no question; but it was in an indirect manner that they produced this effect. They gave rise to dyspepsia and thus caused lithuria and nephritic colic, and finally calculi were passed from the kidneys which were not evacuated from the bladder. These caused irritation of the vesical mucous membrane, and concentric layers of phosphates or urates were formed. The effect of these waters was, therefore, an indirect one; and they not infrequently gave rise to engorged liver, gastric catarrh, and rheumatic and gouty pains.

After some further discussion of the galvano-cautery apparatus presented by Dr. Newman in the afternoon, the meeting adjourned.

When we came out in front of the hotel the full moon was riding high in a clear sky, while below, all over the vast valley of the Hudson, the gray clouds lay banked like the motionless waves of some enchanted ocean. The air was mild and balmy, so that one could sit out of doors with comfort, and the quiet smoke enjoyed while gazing upon a scene so exquisite and impressive is not likely to be soon forgotten by those who were fortunate enough to have that felicity. Some of the party who were especially energetic, and wished to make the most of the limited time at their disposal, actually arose in season to see the sunrise and take a long tramp before breakfast; but the larger number were content to wait to sally forth till after this meal, when stages were in waiting to convey them to Sunset Rock, Inspiration Point, the Kaaterskill Falls and the Mountain House. The Hotel Kaaterskill stands in the midst of the picturesque Kaaterskill Park, through which many miles of charming drives have been constructed, and within a comparatively short distance of the great hotel is to be found a large part of the most beautiful and romantic scenery in the whole Catskill region. An immense outlay, not only upon the house itself, which is the largest mountain hotel in the world, but also

upon its environment, has been made by the proprietor, Mr. George Harding, the famous patent lawyer of Philadelphia, and many superb points which were formerly accessible only to pedestrians can now be reached by carriage roads. There is perhaps nothing finer in the mountains than the grand view of the magnificent Kaaterskill Clove from Sunset Rock and Inspiration Point. From these ravishing outlooks one gets the sweep of the entire Clove; the one commanding the upper portion, with the head at Haines' Falls, and the other the outlet, with the picturesque hamlet of Patenville nestling in the midst of the large gap, and the broad and shining Valley of the Harlem, with its storied river, beyond. You stand upon the brink of a mighty precipice, with the wild Kaaterskill roaring over the rocks nearly two thousand feet below, and directly opposite the majestic dome of High Peak towering to a sublime reach; and here can be met with at times the perfect realization of Ruskin's graphic lines:

"Blue and baseless and beautiful,
Did the boundless mountains bear
Their folded shadows into the golden air.
The comfortlessness of their chasms was full
Of orient cloud and undulating mist,
Which, where their silver cataracts kissed,
Quivered with panting color."

At intervals along the face of High Peak, and emptying into the Clove, are several great gorges, and it is said that the central one of these, known as Buttermilk Gorge, has been pronounced by the artist Mr. Church the most beautiful thing in all the Catskills. Certainly nothing can be more inspiring, to a good mountaineer, than a climb up this wild ravine after a storm, when the water-courses are full. At the foot of the gorge there stood, until a few years ago, one or two buildings which once belonged to a deserted village that has had no Goldsmith to record in imperishable verse its humble story. The village went to decay because the supply of hemlocks on the neighboring mountains gave out, and the remains of the foundations of the old tannery, which was the *raison d'être* of the village, can still be found upon the banks of the stream.

In making the ascent of the gorge one meets with an almost continuous succession of cataracts of the most varied and exquisite beauty for over a thousand feet,

Where through abysses vast of endless green,
In fall on fall, from the stupendous height,
Mid clouds of sparkling spray, with sunlight sheen,
The foaming flood comes leaping down the wild ravine.

In one of the most picturesque of the many falls the feathery water spreads itself completely over a vast wall of rock some sixty feet high and eighty or a hundred feet in width, which is one living mass of the richest ferns and moss, and, dividing into a myriad shining streams, flows down like a shower of diamonds over its glowing emerald bed.

By the time that our excursionists returned to the hotel after their morning's expedition, which for many of them included the descent to the bottom of the enormous amphitheatre into which leap the famous Kaaterskill Falls, they were fully ready to enjoy the

bountiful dinner that they found awaiting them. It is only just to say that both Mr. Paige, the manager, who opened the hotel expressly for the accommodation of the party, and Mr. Harding, who was himself present to do the honors of the house, were throughout indefatigable in their efforts to make their sojourn as pleasant as possible in every way; and the Association was glad to express its appreciation of their courtesy by a cordial vote of thanks to these gentlemen. In the afternoon the company set out upon their homeward journey, and it was with no small feeling of regret that we left the enchanted domain of the misty mountain tops to descend once more into the matter-of-fact world of everyday life.

THE ASSOCIATION OF AMERICAN PHYSICIANS (Limited).

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—"Practitioner's" communication in your issue of July 3d has very pertinently directed attention to the characteristic features of the new organization styled "*The Association of American Physicians.*" He justly states that a body which assumes to be composed of the physicians *par excellence* of America, ought to be conscious that its very assumptions make its members shining marks of criticism, and it should, therefore, be very careful that all its members are really physicians of eminent ability, skill and acquirements; and furthermore, that no men, who are physicians of acknowledged and unquestionable reputation and eminence, are excluded from the galaxy, especially to give place to lesser lights.

A superficial examination of the list of Their Eminencies united to become members of this very exclusive association, shows that while a specious attempt has been made to get specimens from the various sections of the country and the national sources, New York, Philadelphia and Boston have supplied *forty-two* of the *fifty-six* who responded to the call, while the high professional standing of the medical corps of the Army seems to have counted for nothing in the make-up of the Association by its self-appointed sponsors, although the Philadelphia progenitors must have known of the existence of such a man as Ruschenberger, who has been thought fit to preside over the College of Physicians, of Philadelphia; and the Washington begetter must have heard of the present head of the corps, Surgeon-General Francis M. Gunnell, who, during almost forty years' service, of which over twenty have been on shore, has had as wide a professional experience as half the men in the newly-fledged Association, and certainly very much more than one of them, who is represented to have declared that he is "no doctor," and has not written a prescription for twenty years. By the same token, the many years active professional work of Colonel Basil Norris, of the Army, as attending medical officer at Washington, would seem to have as eminently qualified him to represent the military service in an Association of physicians as the "no doctor."

One fact can not fail to impress a casual reader of the names of the seventy-four select elect, namely: that they include among them the leading "sore-heads" who have foresworn their allegiance to the American Medical Association, on account of its action in revising and setting aside the arbitrary doings of its own committee—the original seven—appointed by it to arrange the preliminaries of the International Medical Congress. We might have expected the seven—or at least *five* of them—to be there, for have we not the written declaration of one of themselves that they are "the *most* eminent contributors to the advancement of medical science" in this country? [Ed. *Philadelphia Medical Times*, January 30, 1886, p. 128] and we can not help inferring a coincidence between their resentful antagonism to the American Medical Association and their part in getting up THE Association of American Physicians. Indeed, it is no secret that this Association has only been organized to complete the set of special societies out of which it is intended to create an exclusive general body aloof from the American Medical Association. Whether only the professional *crème de la crème* has been skimmed off will be open to question so long as the constituent bodies comprise surgeons who can not operate, obstetricians who have no acquaintance with parturient women, and new physicians who are "no doctors." If the death of the American Medical Association is to be accomplished, let the drugging not be attempted by such a homœopathic dose.

A. M. A.

Philadelphia, Pa., July 8, 1886.

NECROLOGY.

SYLVANUS NEWELL BIXBY, M.D.

SYLVANUS NEWELL BIXBY, M.D., the eldest son of Rev. N. W. and Ruby Bixby, died at Strawberry Point, Iowa, May 10, 1886, aged nearly 42 years. He was born in Starksboro, Vt., May 16, 1844, and came to Iowa when but 3 years old. Received his education at Wasioja, Minn., and Hillsdale College, Mich. For a time he devoted his attention to teaching, and was quite successful in this capacity, and was for several years principal of the Elkader High School. He received his medical education at Rush Medical College, Chicago, and at Keokuk, Iowa. He married Miss Emily Denton, of Fitchville, Ohio, who survives him. He was a member of the County Medical Societies of Clayton and Delaware, Iowa; of the Iowa State Medical Society, and of the American Medical Association. He was a physician who was beloved and respected by all who knew him. Of genial character, sympathetic, and ready to aid whenever called upon to do so, he attracted many friends, and will in consequence be greatly missed in the community in which he labored. He was regular in his attendance upon local society meetings, and ever ready with something of interest.

The Delaware County Medical Society attended his funeral in a body, and gave expression to their esteem for the deceased in the following resolutions:

"Resolved, That in the death of S. N. Bixby, M.D., a member of Delaware, Clayton, and Iowa State Medical Societies, and of the American Medical Association, our Society and profession have lost a physician of skill and fidelity, an estimable Christian gentleman, and a faithful member, whose industry and high sense of honor have endeared him to his professional brethren as well as to the community, and whose example in both professional and daily life we earnestly commend to all.

"Resolved, That our heartfelt sympathy be tendered to the family and friends of our deceased brother.

"Resolved, That a copy of these resolutions be furnished to the family of the deceased, and to the local press, and that these resolutions be also spread upon the journal of the Society."

WILLIAM EDWIN JOHNSTON, M.D.

DR. WILLIAM EDWIN JOHNSTON was born near Wooster, Wayne county, Ohio, February 16, 1822. Died at Paris, France, February 14, 1886. He was the oldest son of R. C. Johnston, deceased, and was at the time of his death the oldest American physician in Paris, having practiced there for more than thirty years. He took his degree of Doctor of Medicine, at the University of New York, in 1847, after which, for five years, he practiced with his father, at Sidney, Ohio.

In 1852 he visited Paris, and established himself in the Latin Quarter to be near the schools, when he followed the most eminent physicians of the day. At the same time for pleasure and profit, he acted as foreign correspondent for a number of newspapers, and his success as a writer, made him long hesitate in reestablishing himself in active practice as a physician. The first paper which published his letters, was the *Ohio State Journal*, of August 9, 1852. Four months later he wrote a brilliant and exhaustive description of the *coup d'etat*, which placed Louis Napoleon on the throne of France, and his subsequent correspondence with the *Ohio State Journal*, the *Cincinnati Gazette*, the *Commercial Advertiser*, and the *New York Times*, would be found to be a complete history of the third Empire from its beginning until 1868, two years before its fall.

In 1855 he became Paris correspondent for the *New York Times*, under the pseudonym of "Malakoff." His letters from Italy, over this signature rendered him famous as a war correspondent, being as distinguished for their literary merit as for their fidelity to facts; and were a noted feature of that paper, until his regular contributions ceased. Having married Miss Bertha Matteson, of Chicago, in 1866, he found it necessary to devote all his energies to the large and lucrative practice which had grown up gradually around him, in a choice circle of compatriots, and foreigners of all nations. His untiring devotion to his patients has endeared him both as a man, and as physician, to hundreds of families in all parts of the world.

During the last siege of Paris he remained in the beleaguered city, and his services in connection with

the American ambulance were acknowledged by the French Government by the decoration of Chevalier of the Legion of Honor, from which grade he was promoted officer in 1873. He also received from his Majesty the Emperor of Germany, the grade of officer in the order of the Crown of Prussia, in acknowledgement of services rendered German subjects during the siege, and throughout the two months of the Commune which followed. Dr. Johnston's literary education was obtained, not in the schools, but at the printing press, at which occupation he was engaged from the age of 10 years until his graduation in medicine. He was in the true sense of the word, a self-made man, one truly great, whom wealth and prosperity did not and could not spoil. His life was marked by constant acts of kindness and sympathy, and no unfortunate American visiting Europe, applied to him for relief, in vain.

Dr. Johnston in his political sympathies and feelings was intensely American, and he did much to mould French public opinion in favor of the Union during our civil war. His latest published work was his monograph on the Panama Canal Scheme, which so thoroughly showed the imposition practiced on the shareholders, and the impracticability of the undertaking, that the French Government ordered an investigation.

The official notification of the death of Dr. Johnston by the United States Legation at Paris to Hon. Thomas F. Bayard, Secretary of State, contains the following tribute: "In the death of Dr. Johnston the legation loses a valuable friend, one who could always be applied to for any information pertaining to his profession. During the several epidemics of cholera he furnished valuable and reliable information for the use of our Government, as the Records of the Department will show. He also interested himself in the organization of the International Bureau of Literary and Scientific Exchanges and made a report to the Department on the subject containing many valuable suggestions which were practically adopted."

The legation attended his funeral, and sent, on the occasion, to his bereaved widow, a wreath as a tribute to his cherished memory.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

INOCULATION FOR YELLOW FEVER.—The modern expedient for settling knotty points in science is to appoint a Commission; success, it is true, has not uniformly attended this method, and the reports, if not polemical, are generally colorless. Yellow fever is the disease which is now to be investigated in this way. A few years ago, Dr. Domingos Freire announced that he had prepared a vaccine which preserved the vaccinated from yellow fever; his method of experimenting, however, did not commend itself to the bacteriologists; and M. Rebourgeon, who had been trained in M. Pasteur's laboratory, was sent out to Rio de Janeiro to guide Dr. Freire into the right way. The papers since published by these two experimenters confirmed the earlier claims, and M. Rebourgeon has returned to Paris to convince the sceptics; he informed the Société de Biologie at its meeting on May 22, that, during the recent epidemic, 6,000 persons had been inoculated, of whom not one suffered from the disease; and that, in seven cases where patients were inoculated while suffering from the disease, recovery took place in every instance. The Society appointed a Commission of five, including MM. Brown-Sequard and Cornil, to study the method. In the United States, moreover, the demand for a Commission has been backed by the American Medical Association.—*British Medical Journal*, June 5, 1886.

HONORS TO PASTEUR.—The French Humane Society has recently presented a medal to M. Pasteur, in recognition of his services to humanity.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE will hold its fifty-sixth annual meeting in Birmingham on September 1st to 9th, inclusive.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 2, 1886, TO JULY 10, 1886.

Lt.-Col. Chas. Page, Surgeon, leave of absence further extended one month. (S. O. 156, A. G. O., July 8, 1886.)

Major Joseph R. Gibson, Surgeon, granted leave of absence for three months, to take effect about August 1. (S. O. 158, A. G. O., July 10, 1886.)

Major Wm. E. Waters, Surgeon, ordered for duty as Post Surgeon, Ft. Spokam, W. T. (S. O. 112, Dept. Col., July 2, 1886.)

Capt. Edwin F. Gardner, Asst. Surgeon, granted leave of absence for two months. (S. O. 158, A. G. O., July 10, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JULY 18, 1886.

Wentworth, A. R., Asst. Surgeon, detached from the U. S. S. "Brooklyn" and wait orders.

Norton, Oliver D., Asst. Surgeon, detached from the U. S. S. "Minnesota" and to the U. S. S. "Brooklyn."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED JULY 17, 1886.

White, J. H., Asst. Surgeon, granted leave of absence for thirty days. July 12, 1886.

Pettus, W. J., Asst. Surgeon, when relieved at Charleston, S. C., to proceed to Savannah, Ga., for temporary duty.

ORIGINAL ARTICLES.

DISEASES AND DEATHS OCCURRING IN THE MEDICAL SERVICE OF JOSEPH JONES, M.D., 1869-1886,¹

IN THE CHARITY HOSPITAL OF NEW ORLEANS, LA.
WITH PRACTICAL OBSERVATIONS.

Conclusions of value may be obtained by a general review of the results of medical service extending over a series of years. The nature of such conclusions, and their relations to the practice of medicine, must evidently depend not merely upon the number of the observations, but also upon the mode in which they were recorded.

The writer has served in the Charity Hospital of New Orleans, Louisiana, from January 1, 1869, to April 1, 1870, and since that time to April 1, 1886, six months of each year, from the 1st of October to the 1st of April; and during this period, extending over eighteen years, he has kept a careful record of the names, ages, and nativity of the patients, diagnosis, and the final results of the cases treated by him in the wards of the hospital. During this period the total number of cases of disease under his care and immediate treatment was 6311, of which 668, or 10.4 per cent., terminated fatally.

The following consolidated record will form a permanent value for comparison, and for the illustration of the nature and mortality of the prevalent diseases of the delta of the Mississippi:

Tabular Statement of cases and deaths, and percentage and rate of mortality during the various periods specified in the medical service of Joseph Jones, M.D., in the Charity Hospital of New Orleans, La.:

MICROSCOPICAL AND CHEMICAL CHANGES OF THE BLOOD IN MALARIAL FEVER.

The author has been led, by extended observations and investigations, during a period of 30 years—1855-1886—to definite conclusions, some of which may thus be formulated:

1. The phenomena of malarial fever in the human organism are due to the introduction of a morbid ferment.

2. The micro-organism concerned in the production of malarial fever attacks chiefly the best blood corpuscles of man.

3. The phenomena of malarial fever are due in part to the destruction of the colored blood corpuscles, in part to the derangement of the normal chemical changes of the blood and organs, and in part to toxic action of the chemical compound developed by, and resulting from, the action of the micro-organisms.

4. The chemical and physical changes excited in the blood and organs of the human body by the action of the malarial micro-organisms are in their highest and final results inimical to the development and multiplication of the essential potential elements of the malarial ferment.

¹ Read in the Section on Practical Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

5. The active febrile phenomena of malarial fever are, in their ultimate results and products, *antiseptic*; they tend to inhibit the development, and even to destroy the morbid ferment of malarial fever.

6. Many of the most destructive and fatal effects of the malarial ferment occur in cases in which there has been comparatively little elevation of temperature, and in which the paroxysms succeed each other in an almost imperceptible manner.

7. The recurrence of paroxysms in malarial fever is due to the *partial destruction* of the micro-organisms during the active and pronounced chemical changes of the fever. When not wholly destroyed during the febrile stage, the micro-organisms are *re-produced*, and again, at definite intervals, induce disturbances of the nervous system, alterations of the blood, and oscillations of the temperature.

8. Such agents as quinia, arsenic, and the preparations of mercury, act as poisons to the micro-organisms of malarial fever, excite an antiseptic effect upon the blood, bind the oxygen more nearly or chiefly to the hæmoglobin, and proteids, and directly promote the elimination, through the alimentary canal, the skin, and the kidneys, of the noxious products of the morbid ferment and of the increased and altered chemical actions.

9. The changes induced by the morbid malarial ferments upon the blood differ chemically and microscopically from those induced by other morbid organisms, as those of small-pox, typhoid fever, typhus fever, yellow fever, measles, scarlet fever, relapsing fever, diphtheria, Asiatic cholera, Oriental plague, tuberculosis, Oriental leprosy, pneumonia, pleuritis, carditis, erysipelas, rheumatism and pyæmia.

10. The micro-organisms which we have observed in the blood of patients suffering from malarial fever may be thus briefly enumerated:

(a). Minute globular bodies from 10,000 to 30,000 of an inch in diameter, having the general appearance and chemical features of the spores of bacteria.

(b). Globular bodies of larger size than the preceding, often of a dark opaque character, found not only in the *liquor sanguinis*, but also in the colored blood corpuscles and in the colorless blood corpuscles. These bodies, most probably true spores, appear to possess the power of invading and destroying the colored blood corpuscles. These micrococci, or spores, are often observed in the blood, in groups, surrounded by protoplasm constituting zoogloea.

(c). Ovoid, cylindrical and rose-shaped bodies, not destroyed by acetic acid, and stained by anilin dyes. These bodies increase during the cold stage, and are also more numerous in pernicious malarial fever.

(d). Colorless blood corpuscles containing minute pigments, granules, and dark spherical bodies resembling sporules, many of them pigments, corpuscles, or aggregations of dark spherical bodies, surrounded by protoplasm, are about twice the diameter of the colorless blood corpuscles of normal blood; and their behavior under the action of reagents, and also during the process of staining, leads to the view that a portion at least of these bodies must be regarded as vegetable organisms. These

large pigment cells appear to be characteristic of malarial fever.

(e). Masses of hæmatin of various forms, irregular in size and shape, but most generally the sides and portions seen in profile are angular. The deposit of dark pigment masses in the liver and in the brain, in malarial fever, and especially in cases of repeated paroxysms, finds its origin in the changes of the colored blood corpuscles induced by the morbid ferment, or micro-organisms of malarial fever.

There is an actual destruction of the colored blood corpuscles in the living blood, and within the walls of the living capillaries and blood vessels in malarial fever; and this destruction is not referable either solely or originally to the action of the bile acids accumulated in the blood as a consequence of biliary congestion or obstruction during the febrile stage of malarial fever.

We can detect the process of the disintegration of the colored blood corpuscles by the microscope, and detect the very inception of that great pathological change which constitutes one of the most distinctive features of malarial fever, and which must be carefully considered in any scientific and rational plan of treatment.

(f). Marked variations in the size of the colored blood corpuscles. These variations, from small corpuscles to what might be called giant corpuscles, twice the diameter of normal blood globules, appear to be characteristic of malarial fever.

11. *The destruction of colored blood corpuscles* does not take place with equal rapidity in all parts of the organism, but appears to be mostly marked in the spleen and liver. The blood pigment resulting from the hæmatin of the blood corpuscles is frequently observed in the blood as it circulates in the vessels and capillaries, in masses of various sizes, and in the form of cellular elements.

Without doubt local congestion may be caused by obstruction of the circulation in the capillaries by these pigment particles and cells; and such congestion may lead to local hæmorrhages. The congestions and hæmorrhages thus resulting are especially significant when occurring within the structures of the brain and spinal cord.

The appropriation of a portion of the altered coloring matter, hæmatin of the colored blood corpuscles, by the leucocytes, is due to the physical and vital endowments of these elementary bodies.

It is now generally admitted that the colorless blood corpuscles are elementary organisms, which are endowed with the power of spontaneous motion, this power belonging to them in virtue of the protoplasm of which these bodies are composed. This motion is of two kinds, consisting of change of form and change of place; the latter resulting from the former. As movements of this kind are seen in greater perfection in rhizopods and *amæba*, they are called *amæboid*.

The colorless corpuscles, when carefully examined in considerable numbers under high forms of the microscope, $\frac{1}{6}$ to $\frac{1}{4}$ inch objective, are seen to differ from one another both in size and aspect, and in their properties and spontaneous movements.

The careful experiments of physiologists have established the important fact that it is possible to find the colorless blood corpuscles. It has been demonstrated that the colorless blood corpuscles possess the faculty of taking, by virtue of their amœboid movements, solid particles into their substance. This subject is of great interest to the histologist, in affording him a means by which to mark individual corpuscles so as to follow them in their wanderings through the organism, and to the physiologist, in relation to the mode in which amœboid cells take in nourishment; to the student of fevers it is of transcendent importance in giving an important point of diagnosis for malarial fever, which distinguishes it from all other forms, and especially yellow fever.

The author demonstrated, during the progress of his pathological researches, extending from 1856 to 1886, the power of the colorless corpuscles of human blood to feed upon and appropriate the hæmaglobin, hæmatin, and hæmin of the colored blood corpuscles in the blood vessels of malarial patients, before physiologists had experimentally determined, by employing either finely divided fatty substances or coloring matters, the power of the colorless blood corpuscles of taking solid particles into their substance.

We have thus traced the pigmentation of the colorless blood corpuscles in malarial fever to

(a). The destruction of the colored blood corpuscles by the morbid ferment, or micro-organism of malarial fever.

(b). The coloration of the hæmaglobin, hæmin, and hæmatin, and its appropriation by the colorless blood corpuscles in virtue of their physical and vital principles and amœboid movements.

(c). The invasion of the colorless corpuscles by the colored spores of the malarial bacillus.

12. *Increase of water in the blood of malarial patients.*—Chemical analysis has shown that normal healthy human blood frequently yields 150 parts, in the 1000 parts of blood, of colored blood corpuscles in the dried (*anhydrous*) state. The dried blood corpuscles do not represent the true relations of the moist blood corpuscles to the liquor sanguinis of the living human blood as it circulates through the vessels. The number of moist (normal colored blood corpuscles) is obtained by multiplying the dried corpuscles by four. We thus obtain for healthy human blood the following composition:

1000 parts of healthy human blood contains	
Moist red globules,	600
Liquor sanguinis,	400

In prolonged or chronic malarial fever (malarial toxæmia or cachexia) the author has found the dried blood corpuscles to be reduced to 50 parts in the 1000 parts, and in some cases as low as 30 parts in the 1000 parts of blood.

If we accept the first figures, the following will represent my constitution of the blood in chronic malarial poisoning:

1000 parts of human blood in chronic malarial fever contains—	
Moist red globules,	250
Liquor sanguinis,	750

We have in the preceding changes of the blood, induced by the action of malarial poison, an explanation of the sallow, anæmic complexion, the feeble, irritable action of the heart, the depressed muscular power and mental forces, and the bloated countenance, protuberant belly, and swollen, anasarctous limbs.

13. *Diminution of the Fibrin of the Blood.*—The persistent and uniform deviation of this constituent of the blood in uncomplicated cases of malarial fever distinguishes this from the true inflammation and the fever accompanying local inflammation; and also affords an explanation of the tendency to hæmorrhages in many endemics of malarial fever.

PRACTICAL OBSERVATIONS ON THE TREATMENT OF MALARIAL (PAROXYSMAL) FEVER.

Of 2,327 cases of the various forms of intermittent fever (quotidian, tertian and quartan), only 5, or about 0.21 per cent., terminated fatally. The mortality in remittent malarial fever was greater, the deaths numbering 7 in a total of 247 cases; per cent. of mortality 2.83. One-half (50 per cent.) of the cases of malarial hæmaturia terminated fatally; and more than one-half the cases of pernicious congestive malarial fever died; or, more exactly, 56 deaths in 87 cases (64.3 per cent.). The deaths from chronic malarial cachexia were more numerous than in the intermittent and remittent fevers, but less than in the pernicious and hæmorrhagic forms; 14 deaths occurring in 212 cases, or a mortality of 6.6 per cent.

The fatal cases of intermittent fever were complicated with intercurrent diseases. It is evident from the preceding statistics, that the treatment adopted by the author yielded results corresponding with the nature, severity, preceding duration and effects of the various types or varieties of the malarial diseases.

In an effort to formulate the general plan of treatment pursued in these cases, it is evident that the remedies were necessarily adapted to the natural progress and history and visceral complications of each class and condition of the malarious manifestations; and for purposes of clearness and precision and brevity we will present the practical results under the following heads:

I. ACUTE STHENIC, INTERMITTENT AND REMITTENT FEVER, OCCURRING FOR THE FIRST TIME IN HEALTHY INDIVIDUALS.

Numerous cases have come under my observation of treatment of natives of Europe and of the healthy non-malarial districts of the United States of America, who have been attacked by the various forms of intermittent and remittent fever for the first time in the history of their lives. Thus I have seen entire crews of Northern sailors stricken with intermittent and remittent fever shortly after their arrival in the Southern rivers bordered by extensive swamps and marshes.

Natives of Ireland, France, Germany, Italy, Spain and England, who work for the first time upon the railroads and in the swamps, rice-fields and marshes of Georgia, South Carolina, Alabama, Louisiana, Mississippi, Arkansas and Texas, are subject to the most

violent forms of intermittent and remittent fevers in the months of July, August, September and October. Such cases, if imperfectly treated or abandoned to the powers of nature, either perish in the acute stages of the malarious disease, or suffer repeated attacks of chills and fever, and during the repeated congestions of the internal organs, add the oft recurring cold and hot stages, are gradually reduced to a most distressing and dangerous condition. The repeated and prolonged action of the malarial poison induces destruction of the colored blood corpuscles, anæmia, hepatic and splenic enlargements and indurations, aberration, nervous phenomena, neuralgias, muscular prostration, and general anasarca.

Whilst it may be true that a certain percentage of cases of intermittent fever in comparatively healthy localities, especially when the individual moves out of the malarial region in which the disease has been contracted into a non-malarious district, may recover spontaneously without the exhibition of quinine, or any other remedy. This statement does not apply to the swamps, marshes and rice-fields of our Southern States. In these low, moist, malarious districts, the poison of malarial fever is ever present, and while it may slumber and hibernate during the coldest weather of the year, it returns in the spring time, with the vegetation, and attains its maximum intensity in the months of July, August, September and October.

If this disease be often self-limited in its character, and terminates in health either from the elimination of its cause, or the exhaustion of susceptibility to its action, or from the "*curative powers* of nature," such favorable termination is only possible in healthy non-malarious localities, and appears to be wellnigh impossible in such regions as the swamps, marshes and rice-fields of our Southern States.

Many cases of intermittent and remittent fever which appear at the outset to be devoid of danger, frequently assume without warning highly dangerous characters. It is, therefore, manifestly impossible to predict at the commencement of an attack what its subsequent symptoms, course and termination may be. In this disease, in which the virtues of quinine as an *antipyretic* and *anti-paroxysmal* and *antiseptic* remedy, are well established, there is no excuse for delay and indecision; "*to wait for a remission*" may be "*equivalent to the loss of a patient*," and has been justly termed "*a meditation on death*."

Holding these views, the author has used purgatives and quinine at the onset of the disease, and continues the use of quinine in full doses, regardless of the stage of remission or intermission, or febrile excitement. Whilst unloading the portal circle, and relieving the congestion of the brain, liver and spleen by mercurials, quinine also has been simultaneously administered. Thus 10 grains carb. of calomel and sulphate of quiniæ, followed in four hours by one fluid ounce of castor oil and from 5 to 10 gr. of quinine, administered promptly in the onset of intermittent and remittent fever, not only causes free evacuations of the bowels, but also arrests the fever, and places the system in the proper condition for the subsequent action of quinine. Quinine was then

administered in doses of 5 or 10 grains, until from 15 to 40 grains were administered during the twenty-four hours.

After the complete subsidence of the fever, quinine is not abandoned, but administered, from 10 to 20 grains each day, for at least one week after the fever; and subsequently from 5 to 10 grains each day, for at least ten days longer; and where the patient is compelled to remain in the malarious atmosphere exhaled from swamps, marshes or rice-fields, he was advised to use quinine as a prophylactic, often combined with iron and arsenic during the months of September and October.

In those cases in which the stomach was too irritable to retain the quinine, it was used externally or by enema. For external administration the following formula has been found to be useful:

- R. Quin. sulph. ʒi.
 Linam. saponis.
 Olei olivæ. aa ʒiij.
 S. Use as a liniment under armpits (axillæ), on the inner surface of thighs, on the abdomen and spine, every two, three, or four hours.

This liniment is efficient also in the treatment of malarial fever occurring in children, who take quinine by the mouth with great reluctance.

When quinine is administered to the adult as an anti-malarious remedy in intermittent and remittent fever, neuralgia, brow-ague, and in cases of rheumatism, pneumonia and pleuritis resulting from cold, damp and marsh air, and which show a periodic or intermittent character, it should be given *alone*, and in large doses at regular intervals;—thus, beginning with 10 grains, followed by the same or half this quantity (5 grains) every four hours, until the frequency of the pulse is lowered, the fever heat is diminished, and the ears ring. Sugar-coated quinine pills as furnished "by the wholesale" from the manufacturing druggists and chemists, should be universally abandoned by the medical profession in malarial regions, because their insolubility renders them incapable of rapid assimilation by the enfeebled and irritated stomach. The use of these and other manufactured pills often causes the loss of precious time, frequently deceives both physician and patient, and ensures a fatal result when recovery should have been certain, if *quinine* and *quinine alone* had been administered by the mouth or rectum, or by subcutaneous injection. I have seen these sugar-coated quinine pills, and the so-called quinine capsules, pass through the bowels in intermittent and remittent fever unchanged with the discharges of the bowels. When the bowels are in active motion and the doctor is pouring in his "elegant commercial manufactured sugar-coated and gelatine embalmed quinine pills," they may sometimes be heard falling upon the bottom of the chamber rattling like buckshot or dried pease.

In all serious cases of malarious disease, where the object of the physician is to produce a prompt and decided impression, *quinine is best given alone*; each dose may be stirred in a wineglassful of pure water or wrapped up in moistened wafer paper (to be had of any pastry-cook) and swallowed as a bolus. Pills

of the bisulphate of quinia, which may be prepared extemporaneously, with dilute aromatic sulphuric acid, may be used in some cases with benefit, but it sometimes occurs that this form of the sulphate is too irritating to the gastric mucous membrane. In like manner the solution of the quinine in water by the aid of citric or sulphuric acid may prove useful, provided the acid solutions do not irritate the stomach.

As a general rule, I have not employed digitalis, aconite, veratrum viride and gelsemium in intermittent and remittent fever, but trusted chiefly to the sulphate of quinia. In like manner, opium, hydrate of chloral, morphia, belladonna, hyoscyamus and the bromides, were used as adjuvants to quinine when necessary. Without doubt digitalis, veratrum, gelsemium, opium and its preparations, chloral hydrate, chloroform and bromide of potassium may be indicated in certain cases, and I have used one and all of these drugs to fulfil certain indications, but I have never lost sight of the fact that *quinine* was the great agent for the arrest and cure of the paroxysmal fevers. Chloroform used in large doses to arrest or abort the cold stage has, according to my experience, proved destructive to life, when administered by others. I regard the practice of giving large doses of either chloroform or tincture of digitalis in the cold stage of malarial fever as dangerous. Salicine, salicylic acid and salicylate of soda have proved useful in the treatment of the various forms of fever, and especially in rheumatic fever, as depressors of temperature, and even as cathartic agents in malarious fevers, but these remedies have never, in my hands, equalled or superseded the sulphate of quinia.

2. INTERMITTENT FEVER OF LONG STANDING.

The prolonged action of the malarial poison will often cause congestion of the internal organs, induces profound alterations in the blood, and structural changes in the liver and spleen. The frequent occurrence of *interstitial hepatitis* and jaundice, as well as irregular action of the heart, debility of the capillary circulation and general anasarca, characterize the chronic stages of malarial fever. The indications for treatment are:

1. To arrest the paroxysms.
2. The regulation of the hepatic and renal secretions.
3. The restoration of the impoverished and watery blood to its normal condition.
4. The improvement of digestion and assimilation, and the restoration of the nervous and muscular forces.

To accomplish the first indication, quinine and arsenic are most reliable agents. The latter should be administered in such doses as not to irritate the stomach. Comparatively small doses of arsenious acid, administered at regular intervals, often accomplish great good in obstinate, protracted cases of malarial fever. I have freely used Fowler's solution of arsenic in doses varying from 6 to 12 drops, every four, six or eight hours. Ten drops of Fowler's solution, given one hour after each meal, has been beneficial in protracted intermittent fever, marsh cachexia; and especially when the tincture of iron was

administered (properly diluted) in similar doses, one hour before each meal, in order to fulfil the third indication. Quinine was also administered in these chronic cases, according to the indications, in from 3 to 6 grains three times a day. The quinine was frequently added to and administered with the solution of the tincture of iron.

During convalescence, infusions of Virginia snake-root (*aristolochia serpentaria*) and of quassia were used, with the result of improving digestion and increasing the muscular force. Nux vomica (in powder, extract or tincture), and solutions of strychnia, proved of permanent benefit in protracted cases, especially when administered in conjunction with tincture of iron and the mineral acids.

In hepatic derangements caused by the action of the malarial poison, nitro-muriatic acid, administered internally, and applied externally in the form of the footbath, or used locally over the region of the liver, possesses great value. The tincture of iron, as well as the nitro-muriatic acid, possesses the power of giving tone and power to the muscles, and especially to the muscular fibres of the heart—a remedy of great importance in the anæmic state induced by the action of the malarial poison.

Although apparently not reduced in flesh; but, on the contrary, with bloated and swollen countenances and limbs, the miserable anæmic, sallow victims of the prolonged action of the malarial poison suffer from a feeble cardiac action, often accompanied with a murmur; they are incapable of prolonged muscular effort, panting for breath upon the slightest exertion, and suffering with violent palpitation of the heart, dizziness and imperfect vision. The distress is often very great when such patients attempt to ascend the stairs; the heart beats tumultuously, the "head swims," and the trembling patient sinks down exhausted—overwhelmed by muscular and nervous weakness, and irregular action of the circulatory and respiratory apparatus. Both the cerebro-spinal and the ganglionic (sympathetic) systems are depressed in their action and deranged in their functions; and the ganglia of the heart are necessarily deeply affected by virtue of their increased activity in sickness as well as in health; and the muscular fibres of the heart, supplied with anæmic blood, containing the micro-organisms of malarial fever and the noxious results of their chemical actions, necessarily manifest feeble and spasmodic actions.

Under the judicious and persevering use of quinine, iron, arsenic, strychnine, and the tribasic phosphate of iron and lime, these distressing symptoms gradually pass off; the patient loses the local cardiac murmur, the action of the heart becomes slow, regular and vigorous, the cerebro-spinal and sympathetic systems regain their tone and vigor, the intellect is again able to perform its functions, the liver secretes normal bile, the blood regains its lost colored corpuscles, the surface of the face and body resumes its healthy appearance, and the patient is able to resume his normal occupation.

It is well known that neuralgia of a strictly periodical character often prevails in the same localities and seasons, preceding alternately with and succeed-

ing to periodical fevers, exhibits the same types and phenomena of intermission and remission. Periodic neuralgia is therefore produced by the same morbid ferment as intermittent and remittent fevers, and yields most readily and surely to the same general plan of treatment. In this painful and most distressing manifestation of the malarial disease our reliance must be in the free administration of quinia, often combined with opium, morphia, hydrate of chloral, belladonna, and hyosciamus. One-fourth of a grain of morphia with gr. $\frac{1}{16}$ to $\frac{1}{8}$ of atropia, injected subcutaneously, has proved beneficial. Morphia and the preparation of opium should be used with caution by the physician in obstinate cases of neuralgia, in order that the "*opium habit*" may be avoided.

3. PERNICIOUS OR CONGESTIVE MALARIAL FEVER.

In the algid form characterized by rapid, feeble pulse, cold extremities, and prostration of the nervous and muscular forces, when the intellect is clear, the main indications are

1. To bring the patient under the influence of quinine at the earliest practicable moment.

2. To restore the general and capillary circulations, and invigorate and support the action of the heart by the judicious administration of diffusible stimulants and by the external application of sinapisms and heat.

In cases characterized by coma, blisters should be promptly applied to the back of the head and neck, and on the epigastrium, and if the bowels are not loose, a full dose of calomel should be administered by the mouth. Notwithstanding the profound coma which characterizes this class of cases, pressure over the region of the stomach and loin will almost always elicit groans, cries and signs of distress from the patient. The author has been led, by the results of his extended experience in civil and military practice, to regard the prompt application of a large blister, six by six inches, or eight by eight inches, over the region of the stomach and loin, as a measure of great value, which may, in some instances, be the means of preserving life.

The use of such agents as chloroform, digitalis, aconite and veratrum viride in the pernicious forms of malarial fever, according to the experience of the author, is attended with great danger. The injudicious use of chloroform and of tincture of digitalis has, in some cases, caused death by depressing still further the feeble nervous cardiac powers.

The large proportion of the so-called *congestive* cases have been the victims of the prolonged action of the malarial poisons before the sudden development of the dangerous (*pernicious*) symptoms, and manifest the profound action of the malarial poison in the sallow, anæmic, jaundiced countenance, and enlarged liver and spleen. In fatal cases the cortical substance of the brain is frequently found of a dark, almost chocolate color, from the deposition of pigment granules and pigment cells within and around the cerebral capillaries, the pigmentation being most marked in the gray substance of the cerebrum and cerebellum. The enlarged liver presents marks of interstitial hepatitis, with deposits of blood and bili-

ary pigments in the capillary net-work of the lobules. The enlarged spleen resembles a bag of soft, dark, purplish-black mud, and has so little consistency that it can with difficulty be removed without rupture of its capsules and trabeculæ. This black splenic mud contains, in addition to the other constituents of the blood, numerous pigment particles and pigment-cells.

The hopeless character of many of such cases is fully revealed by the results of post-mortem examinations, and the tedious character and slow progress of those which recover is in like manner rendered evident.

If the physician succeeds in arousing his patient from the "*fatal*" paroxysm, his subsequent efforts to restore the blood and organs to their normal condition must be based upon his knowledge of the characteristic lesions of malarial fever, and the therapeutic value and application of quinine, arsenic, and iron. Change of climate is of great importance in the after-treatment of the pernicious forms of malarial fever, but few patients have the necessary means to enable them to make the change of locality and climate.

4. HÆMORRHAGIC MALARIAL FEVER; MALARIAL HÆMATURIA.

Hæmorrhagic malarial fevers prevail in certain seasons and in certain localities, and appear to be aggravated by the dangerous system of *rice culture*. The year 1880 was characterized by the prevalence of severe forms of malarial fever, often attended with hæmorrhage from the stomach, bowels and kidneys. This hæmorrhagic malarial fever prevailed in greatest severity in all those portions of the Delta of the Mississippi in which rice was cultivated, namely, from the mouth of the Mississippi to the hills of North Louisiana and Tennessee. Those cases which came under the immediate observation of the author, in 1880, presented all the symptoms and characteristic lesions of chronic malarial toxæmia, various degrees of hepatic derangement and jaundice, profound anæmia, sudden remissions and intermissions. Beyond a tendency to passive hæmorrhages, these cases presented nothing in common with yellow fever. Even under the most energetic and judicious use of such remedies as quinine, tincture of iron, and fluid extract of ergot, the results were unsatisfactory and uncertain, and a large proportion of the cases terminated fatally.

Fortunately, hæmorrhage from the kidneys is of comparatively rare occurrence during the progress of malarial fever in many portions of our Southern and South-western States; and the form of malarious disease called *malarial hæmaturia*, is comparatively rare in New Orleans. If the kidneys suffered equally with the liver and spleen in the periodic congestions of the various forms of malarial fever, this would prove to be an almost universally fatal disease.

The results of treatment in malarial hæmaturia will depend largely upon the extent and character of the lesions of the kidneys.

When these organs are profoundly involved, and hæmorrhage occurs extensively into the Malpighian capsules and fubriili uriferi, the function of these

organs is necessarily greatly impaired, and often completely arrested, and the patient dies from uræmic poisonings and in convulsions. In most cases of malarial hæmaturia, the physician has to deal with the profound lesions of the blood, nervous system, liver and spleen, induced by the preceding prolonged action of the malarial poison; it is therefore not to be wondered at that many and very diverse plans of treatment have been recommended in this most dangerous and fatal form of disease.

No specific rules can be laid down to meet the indications of each and every case; many are so slight as scarcely to be ranked with malarial hæmaturia, and recover under the most mild measures; whilst in others the lesions preceding and attending the attacks are so grave as to preclude all hope from any plan of treatment now known to the medical profession. In those cases in which the author has been able to institute chemical analyses of the blood, the fibrin has been increased to a marked degree, and in every case he has found derangements of the hepatic functions and secretions.

Benefit has been derived in some cases by combining small doses of calomel with full doses of the sulphate of quinine. The fluid extract of ergot and the tincture of iron have accomplished good in some cases. When the patient vomits incessantly large quantities of green and blue bile, and at the same time is affected with profuse discharges (sometimes bloody) from the bowels, quinine, calomel and other remedies can be administered neither by the mouth nor rectum, and the physician must resort to inunction, and to subcutaneous injections. Quinia, morphine, and minute quantities of atropia, also the fluid extract of ergot, have been administered hypodermically with benefit.

(To be concluded.)

ON THE USE OF SO-CALLED ANTIPYRETIC DOSES OF QUINIA IN TYPHOID PNEUMONIA.¹

BY O. T. SCHULTZ, M.D.,

OF MT. VERNON, IND.

The practice of administering large doses of quinia in pneumonia, which originated in the German antipyretic school of therapeutists, and was recommended by them as a substitute for, or rather as an auxiliary to, the cold bath, does not seem to have found much favor with the American physicians; for referring to latest authors only, we find it not at all mentioned by Davis in his book on "Practice," and very inadequately mentioned by Loomis in Pepper's "System of Medicine." And yet quinia in large, so called antipyretic, doses, properly administered, is a very careful and a very valuable therapeutic measure in the treatment of pneumonia, and more especially of its typhoid form, and merits more confidence than has been hitherto bestowed upon it, not, however, it would seem to me, on account of its power to reduce the temperature, to which Loomis and the Germans

would limit its beneficial action in pneumonia, but on account of some power *sui generis* which quinia seems to exert on the diseased process of low essential fevers.

It shall be my aim to show to-day, 1st, what effects accompany the methodical exhibition of so-called antipyretic doses of quinia to cases of typhoid pneumonia, and, 2d, what precautionary rules must be observed in administering such doses.

Before entering upon the subject at all it will be necessary for me to briefly define my position on certain mooted points that have a bearing on the question at issue, such as to the action of typhoid pneumonia, as to the relation of malaria to the pneumonias that occur in our region of country, and as to the manner in which quinia benefits essential fevers that have a marked tendency to asthenia. I will first state that Mt. Vernon is a small country town near the confluence of the Ohio and Wabash rivers, and that my practice largely lies in the "bottoms" of these rivers, and among farmers more or less exposed to the vicissitudes of a country that is being more opened up and brought under cultivation. Also that from May, 1875, to May, 1886, I have had under observation 238 cases of croupous pneumonia, but few of which presented the sthenic type, and that owing, as I claim, to the course of treatment pursued, I have had the low mortality of 6.50 per cent. Further, that in addition to the quinia administered according to the rules presently to be given, my typhoid pneumonia cases received phosphide of zinc as soon as the symptoms took on the "typhoid" character, and that camphor, or in advanced stages, digitalis and camphor, were resorted to as soon as signs of cardiac failure began to appear.

As to the action of "typhoid" pneumonia, increased opportunities of observation force me to still maintain the opinion expressed by me in a paper entitled "Observations on Pneumonia," *American Practitioner*, August and September, 1879, p. 94, *et seq.*, that this form of pneumonia is not a distinct entity of disease, nor due to a potential causative principle, but "that it is a croupous pneumonia, that in our enfeebled constitution runs an adynamic course;" and that "gives a cause sufficient to produce a croupous pneumonia of moderate severity and the constitutions, such as the far larger portion of our patients present, and the disease must necessarily run a typhoid course."

My position as to the complication of malaria with pneumonia is expressed in the same paper, p. 97, in the following words: "The complication with malaria manifested itself in the same way and pursued the same course as when malaria is superadded to any other disease; and as little as we would be justified on this account of speaking of a miasmatic bronchitis or a miasmatic pertussis, would it be proper to call this even miasmatic pneumonia with Wood and Da Costa." I would add that except in cases in which a direct complication of the two diseases was present, when the exacerbations of the fever at the time of the ague paroxysms, with the consequent enormous increase in all subjective symptoms might well give color to the invention, by inaccurate ob-

¹ Read in the Section on Practical Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

servers, of the myth of an intermittent or remittent pneumonia, with the imagined disappearance of all *objective* symptoms of the disease in the intervals between the paroxysms, *malaria showed its influence only in its vitiating effects upon the constitution of my patients, in weakening their powers of resistance and invaliding important organs.* Judging by what I have seen of "bilious" pneumonia, this variety of pneumonia, which also is claimed to be brought about by a complication of pneumonia with malaria, has no more right to independent existence than intermittent or remittent pneumonia. Extension of the gastric catarrh to the duodenum and to the bile ducts frequently enough gave rise to the so-called "bilious" symptoms; a mild degree of icterus was also usually present, and in a few cases there was marked jaundice, but in no case could these symptoms be set down as due to malarial infection.

How quinia accomplishes good results in the treatment of typhoid pneumonia has not as yet been determined. I opine that it is not by its fever lowering property, for I have seen the general condition of my patients improved even when no impression was made on the temperature; and then, the pyrexia of our typhoid pneumonia is rarely very high, the temperature but rarely exceeding 103° , and varying usually from 101° to 103° . I have never seen a temperature above 105° , and a range from 103° to 105° was found in but a few cases during a year's practice. Yet notwithstanding this low grade of fever, our typhoid pneumonia is a very *fatal* disease, and quinia given in large—antipyretic—doses may not reduce the morning temperature at all and yet very favorably influence for good the course of the disease. There seems to be inherent in quinia, when given in large doses, a specific power of so influencing diseases attended with great and rapid tissue metamorphosis, and retention of the waste products of such tissue changes in the system, that these diseases take on a more favorable course and come to a more happy issue under its use. The same conclusion seems to apply to pneumonia that I draw for typhoid fever. "It would seem that quinia neutralizes in the system or discharges therefrom the causes or the products of the typhoid fever poison, and that its influence is not limited to the time the drug remains in the body, but continues until these causes of typhoid fever, or the waste products of the same, have been removed or have reaccumulated." (*American Practitioner*, November, 1885, p. 287.) The influence of quinia on the temperature is in these fevers a matter of secondary importance; moreover, its antipyretic action seems to be an outcome of its specific power, for it is greatest and most searching in those fevers in which tissue metamorphosis forms an important factor in the maintenance of a high degree of pyrexia, while it is far less outspoken in those diseases in which fever seems to be due more to an exaltation of the nerve centres.

But if quinia has this specific action on essential fevers with adynamic tendencies, and the reduction of the temperature is but one of the manifestations of this virtue, the indication for the employment of this remedy in these fevers must not be sought in

the pyrexia with which they are attended, but in the nature of the disease itself, and the quinia must be administered in such a manner as to best obtain its fullest specific influence, be the fever a pyrexia of a high or a low grade. This is accomplished by giving the drug in a *form* in which it is most rapidly and most completely absorbed; in a *quantity* that will insure its full physiological effects; at a *time* when the height of its action will tally with the normal diurnal declension of disease; and in a *frequency* that a new dose is introduced as soon as the beneficial effects of the previous one have become exhausted. This method I have followed out for over ten years in typhoid pneumonia, and since 1881 in typhoid fever, and its advantages in the treatment of the latter I have endeavored to show in my paper, "Has Quinia a Specific Action on the Diseased Process of Typhoid Fever?" (*American Practitioner*, November, 1885.)

The method pursued by me, and the objects I seek to accomplish by this methodical use of quinia in these fevers, appear to be identical with the course followed out and the ends striven for by Pecholior in typhoid fever, as reported by Charcot to the French Academy of Sciences (vid. *Therapeutic Gazette*, November, 1885, p. 770).

1. What effects attend the methodical administration of large doses of quinia in typhoid pneumonia? I shall discuss this question under the following heads: 1, the effect of quinine on the temperature; 2, on the heart; 3, on the lungs; 4, on the course and the termination of the disease.

The Effect of Quinia on the Temperature.—A dose of quinia given in the evening will usually cause reduction of the morning temperature of 2° to 5° , the temperature beginning to fall within an hour after the taking of the quinia and continuing to decline for a number of hours, the fall being attended with a profuse sweat or not, and accompanied with more or less signs of prostration, which at times amount to partial collapse. In a certain number of cases the morning temperature is as high as it was before quinia was given. It is impossible to foretell in which cases the temperature will not be reduced; the fever may be of a high or of a low grade, and the disease in its earlier or later stages. The cases in which this occurs are not numerous, but they always prove obstinate and dangerous. During the day following the administration of quinia the temperature again gradually rises, and either by night or, in more favorable cases, by the evening following, the temperature is as high or higher than it was when the quinia was given.

The impression which quinia produces on the temperature is more pronounced during the latter than during the earlier part of the disease, and even in cases that terminate fatally the temperature is still greatly influenced by the quinia during the latter half of the pneumonia, but its action is more evanescent, a higher temperature replacing the lower more quickly. Defervescence may follow any of the doses of quinia, the temperature either falling to the normal and not again rising within a few hours, or the declension not being so great, and the fever again

rising to less than the former height by the next evening, and then gradually and steadily falling to the normal within the next twenty-four or forty-eight hours. A profuse perspiration usually accompanies the falling of the temperature. It may, however, be absent, or only a slight moisture may be present, even when the morning temperature is greatly lowered. The sweat is more often absent or but slight during the earlier days of the disease, while during the latter days it is rarely absent, and a profuse drenching and offensive flow usually occurs after every dose. These sweats seem to be of favorable import; the patient's condition is better in the morning when the sweat has taken place, even when the temperature is not much reduced; besides, the absorption of the exuded nausea seem to take place more rapidly when the sweats are profuse.

The Effect of Quinia on the Heart.—After an evening dose of quinia the pulse in the morning is stronger, fuller, slower by ten to thirty beats, more regular, if dicrotism or intermissions were present, these have disappeared; the heart's action is prompter, stronger, more distinct, the valves close more sharply and more completely. This improvement is independent of any effect on the temperature, for I have repeatedly observed it, where the temperature would have remained entirely unaffected by the quinia. There comes a time in severe cases of pneumonia, when the heart's impulse is imperceptible to the eye or touch, when its area is enlarged, the action is indecisive, without power, hesitating, the beats are unequal in form and as time progresses become unequal also in time and rhythm and intermittent; the sounds are widely diffused, it is impossible to locate them, they are indistinct, muffled and accompanied with a blowing sound. The pulse with this condition of the heart is empty, hesitating, barely perceptible, some beats fail to reach the finger. This condition of imminent heart paralysis is not brought about by the high temperature alone, for I have seen it in cases that have never registered more than 103° and that only for a few evenings, but is due to an innate weakness of the cardiac muscle in persons broken down by previous disease, bad nourishment, exposure, intemperance, overwork and old age. If a large dose of quinia be administered in the evening and care be taken to guard the feeble heart against the early depressing effects of the remedy, the heart's action becomes steady, strong, and more effective, a load seems to be removed from the heart. This effect may be obtained time and again in the same case, until either the improvement becomes permanent with established resolution and defervescence, or else the symptoms of cardiac exhaustion become more and more pronounced after each temporary improvement and finally culminate in paralysis. I have learned to regard one behavior of the pulse with great apprehension, and as an indication for an early beginning of the quinia treatment. In many cases, which show all signs of the adynamic and the local symptoms of "typhoid" pneumonia, the pulse with a temperature of 103 and over remains remarkably slow, 80 to 100, for so severe a disease, and for the amount of prostration that is present, it

is thus hard, strong, regular, equal, some cases show dicrotism, in others this is absent, suddenly the heart breaks down without any increase in the fever, sometimes early in the course of the disease, but more usually by the fifth or sixth day. These cases are hard to rally, the signs of cardiac exhaustion once being established; the heart can by constant spurring, be made to perform its work moderately well for three or even four days, but at last it fails. I have seen such cases in the old as well as the young.

When the temperature of the fever has been reduced to nearly normal by a large dose of quinia, the pulse is usually also reduced to 80 or 88, though sometimes it remains more frequent. It differs, however, greatly from the soft, compressible pulse of final defervescence, the pulse of the quinia apyrexia being hard and sharp. It retains this character for some hours, and then becomes soft and frequent, several hours before the thermometer in the axilla will detect any increase in the fever. As the temperature ascends to its former height, the pulse resumes the character which it had before the quinia was given.

The Effect of Quinia on the Lungs.—The frequency of the respirations is somewhat diminished after a dose of quinia; not, however, in equal proportion with the frequency of the pulse. Thus, while the pulse-beat may be reduced to 80–88, the respirations may still register 28–32. Quinia does not prevent hyperæmia of the lungs, nor does it hinder hepatization from taking place, as new lobes will be invaded during the course of pneumonia even when the system is fully cinchonized. Thus in a boy of 20, in whom a lower right pneumonia was recognized on the second day, and who was taking quinia gr. 10 at 6, 9 and 12 o'clock on the third and fourth days, because a chill coming on at 4 P.M. of each day made me suspect malarial complication, hyperæmia and congestion were made out in the lower left lung in the afternoon of the fourth day, and hepatization was completed by the fifth day. And in a man, æt. 44, in whom a lower left pneumonia was discovered on the first day, and quinia gr. 10 was given at 6 P.M. and at 6 A.M. of the third day, because a chilly sensation would occur every morning, infiltration of the middle right lung was made out on the third day, two hours after the last dose of quinia had been given, the temperature at this time being 99, and the patient being in a violent chill. I have several similar cases on record.

Quinia does not hasten resolution, but it seems to stimulate absorption when once resolution has set in. In cases in which a new lobe would be involved in the course of the pneumonia, the lobe originally affected may clear up and become resonant within a few days. I have seen this when the expectoration would hardly amount to a tablespoonful during the twenty-four hours, and when the case would eventually terminate fatally.

Quinia retards the development of œdema, and even causes the retrocession of its milder grades. It has, however, no influence over fully developed and far advanced œdema. On the contrary, it seems that during the stage of depression that primarily follows the quinia, notwithstanding the most careful husband-

ing of the patient's vital powers, oedema may develop to such a degree that the lungs are overwhelmed thereby.

The Effect of Quinia on the General Condition of the Patient.—The patient's general condition is greatly improved by the quinia. The dry tongue becomes soft, the sordes disappear, the mind becomes clear, delirium vanishes, and even when the disease is destined to terminate fatally, and exhaustion is immense, a partial stupor is the only brain symptom present during the period of improvement that follows after the evening dose of quinia. The bowels give no trouble. The passages rapidly diminish in frequency; thus, in a case seen a few days ago, there were twelve stools per diem before quinia was given. After the administration of quinia gr. xxx the number was reduced to four, and after the next dose to two, at which they remained until convalescence was established. The patients hold their strength better, are able to help themselves, retain perfect control over bowels and bladder, and while under the influence of the quinia do not present much evidence of the gravity of their condition.

The Effect of Quinia on the Course and Termination of the Disease.—Since my typhoid pneumonia cases are always treated with phosphide of zinc and the large doses of quinia, it is not difficult to determine the influence of quinia on the course and the termination of the disease. This form of pneumonia pursues, under the treatment adopted by me, a very mild course; severe brain and bowel symptoms are absent; the heart is protected, and when it flags can usually be spurred on to pursue its work efficiently; oedema sets in late, its milder grades are recovered from, and death in the severer grades is pushed out many days; the pneumonic exudate pursues its normal course to perfect resolution—purulent infiltration I have met with but a very few times; the patient's strength is preserved remarkably well, and he needs less careful and less intelligent nursing; his convalescence is rapid and complete; the mortality is greatly reduced.

I cannot say whether the *duration* of the disease is shortened or not. Typhoid pneumonia is at the best a tedious disease, resolution rarely or never occurring before the eighth or ninth day. At times, we confidently look for resolution from day to day, but it fails to come on, the treatment serving merely, it seems, to keep the vital machinery in motion, but not powerful enough to spur it on to bringing the disease to a close; or if resolution does occur at this time, the bronchi are overcrowded with loosened exudations, which there is no cough to expel. Such cases clearly prove that quinia exerts no power over the *local* manifestation of pneumonia; but that, as in typhoid fever, it moderates the *systemic* disease and protects the organism against its ravages.

What Rules must be Observed in Administering Quinia in Typhoid Pneumonia?—In order to obtain good results from quinia in typhoid pneumonia certain principles must be carefully observed in the administration of the remedy: Quinia must be resorted to *early* in the course of the disease, as soon as the "typhoid" character of the pneumonia becomes ap-

parent. The *disease itself* constitutes the indication for the exhibition of the drug, and the indication is modified by excessive temperature and by an early failing of the heart, only in so far as these furnish extra grounds for the giving of more frequent and larger doses.

An ordinary pneumonia, that shows no typhoid symptoms, without an excessive temperature demands no quinia at all; although, knowing how suddenly and how usually a change into an asthenic condition occurs in the cases that I have to treat, I make it a point to begin giving large doses of quinia regularly by the *fifth* day to these cases also.

If the disease shows adynamic symptoms from the first, or runs along with a temperature above 103, or in individuals in whom I anticipate early cardiac exhaustion, quinia is given as soon as the pneumonia is recognized. The quinia should be given in one large dose, gr. xv, xxx or more, in solution with muriatic acid, at about 7 o'clock in the evening. This dose should be given *every* evening if the evening temperature range 102° or over, or if with a lower temperature the heart is very weak. It should be administered *every other* evening if the patient's condition is good, the temperature of low grade, and the heart's action steady.

This course is to be kept up until the evening temperature is normal, defervescence having taken place, or until it shows by a steady fall from evening to evening that the disease is about to terminate by lysis.

The *size* of the dose, the *manner* of giving the quinia and the *time* when it must be given, are of the utmost importance. It is surprising that at the present time practitioners should continue to administer 1, 2 and 3 grains of quinia every two or three hours in malarial fevers, and then complain that they must resort to iodine, carbolic acid, etc., in order to relieve these patients. Equally astonishing is it to find at this day, when pharmacological record and a mass of clinical experience have settled certain questions with regard to quinia beyond a doubt, physicians exhibiting quinia in 2, 3 or 5-grain doses every three or four hours in pneumonia from the beginning, and then hear them announce that they derive no benefit from this drug, or attribute fancied advantages to the remedy that are plainly due either to accident or to the line of treatment pursued side by side with the quinia. The dose of quinia must be *large, very large*, and given at *one* time, to insure the full physiological effects of the drug, and it must be administered not in a capsule or in a weak solution, but in an *acid solution*, so that its rapid absorption may be made certain. As to the *time*, the normal deviation of the body heat must be borne in mind, and the dose given at an hour when its effect will aid the powers of nature to lower the fever. The natural tendency is to a lower morning temperature, and this tendency must be taken advantage of and the normal morning downfall must be emphasized by a large dose of quinia given in the evening.

The prostration that follows shortly upon taking the quinia must be guarded against. It may be very great and almost amount to collapse, and during its

presence the dreaded œdema may establish itself, or if previously present may be fatally increased. It is always a momentous question with me to weigh in a case of far advanced cardiac enfeeblement the indefinite resisting power of the heart, against the equally indefinite results of the dose of quinia I think necessary to administer to my patient. If, however, I have made mistakes in deciding this question, it has so far always been in underestimating the vital powers of my patient, and overestimating the injurious effects of the medicine. For when I review my fatal cases, it is always for withholding the quinia, or giving it in inadequate doses at the critical time, that I have to blame myself.

The precautions against a dangerous prostration of the vital powers from the quinia vary with the greater or less feeble condition of the patient's heart. If the heart's action is good, regular and equal, no special guard is necessary. But if there is inequality as to force, time or rhythm with an empty pulse present, the dose of quinia should be preceded for a quarter of an hour by two or three table-spoonsful of old whisky or brandy taken next and followed as soon as great perspiration and a sinking of the strength becomes manifest, by three to five grain doses of camphor repeated hourly until the danger is over. In cases in which heart failure is fast developing with the symptoms of dilatation and insufficiency detailed above, digitalis and camphor given every three hours during the twenty-four hours, will usually so tonic the cardiac muscle that with the precedent dose of whiskey, no very dangerous symptoms will become manifest from the quinia.

In the above I have attempted to give with some minuteness, the conclusions gathered from my experience with large doses of quinia, administered in a systematic manner, in typhoid pneumonia. The importance and dangerous character of this form of pneumonia and the frequency with which the general practitioner has to deal with it, the good results that have attended the use of large doses of quinia in this disease in my hands, and the apparent want of agreement among physicians as to the value of this line of treatment are my reasons for presenting this subject to you to-day. Although I may not have advanced much that has not been said before by abler men in a better manner, still I shall rest contented if I have succeeded in directing attention anew to this subject and have thus contributed my share toward confirming this so successful mode of practice in so common and dangerous a disease, and toward making it one of the certainties of the therapeutics of the future which it ought to become be the theory by which we attempt to explain its good results, what it will.

THE THERAPEUTICS OF SUBNITRATE OF BISMUTH AND ASCLEPIA TUBEROSA.¹

BY AMOS SAWYER, M.D.,

OF HILLSBORO, ILL.

That acology has been inexcusably neglected at

¹Read at the Annual Meeting of the Mississippi Valley Medical Association.

our society meeting, is a matter of record, and this certainly is not on account of the want of material, surely not because the subject is unprofitable, for it is one of primary importance, and one that every active practitioner can, if he will, assist, if not by adding to, at least by verifying or repudiating the remedial effects credited to each one of the host of agents which go to make up the long list in our *materia medica*, that he may have prescribed. It would seem to be natural for the mass of the medical profession to receive the expressed opinions of a few noted members as to the efficacy of some new remedy or cause for disease, as verity itself, and overstepping the lines marked out, like magic it becomes the cure-all or cause-all of the day, and until reaction comes, in its own natural time and way, it is useless to attempt to stem the tide. To prove that this statement is true, I need only mention cocaine and the germ theory. It would seem that we could say with Ruskin: "I have little faith in my opinion until I have changed it three times." With this digression I will pass to the consideration of the subject of this paper.

Of bismuth, Pereira, in the first and second edition of his "*Materia Medica*" says: "The metal is first mentioned by Agricola, in 1529, and was termed by the Germans, Wismuth, so called says Matthesius 'because it blooms like a beautiful meadow on which there are variegated flowers of all kinds.' On man it acts locally as an astringent, diminishing secretion. On account of the frequent relief given by it in painful affections, it is supposed to act on the nerves of the viscus as a sedative. It has also been denominated tonic and anti-spasmodic. It was administered in cramp of the stomach, sickness and vomiting, a remedy for waterbrash, in intermittent fever, spasmodic asthma, and as an ointment in chronic skin disease. Hahnemann recommends a portion to be introduced into a hollow tooth to allay pain." Bartholow in his "*Practical Treatise on Materia Medica*," 1877, when speaking of the subnitrates says: "They are somewhat stringent and relieve intestinal movements. As they are nearly insoluble they pass down the intestinal tract and are converted into sulphides." The "*National Dispensatory*," 1884, adds nothing of value to the above.

From this, it would appear that up to the present day it has been administered empirically. Now one, and I believe that it is the *principal* therapeutic effect, lays in its power to coagulate mucus, which may be easily demonstrated by the same process that led to the discovery of this most important property. For a country physician, I have treated a large number of cases of nasal catarrh and various diseases of the throat. After washing out the nose with a solution of subnitrate of bismuth I discovered that the mucus it contained separated from the water in a coagulable mass and that the membrane was in a most admirable condition for application of the local remedies indicated. So also in post-nasal disease where the pharyngeal follicle becomes involved and exude a tenacious glairy mucus which may be moved backward and forth but resists all ordinary means for removal; in such cases, the dry powder dusted upon

it, will in a short time, coagulate the mucus and put the parts in a condition for the reception of those remedies which while it was so covered protected the parts as effectually as if they were hermetically sealed.

In the summer complaint of children as well as in gastric catarrh, where the follicles of the stomach exude the same character of mucus we meet with in nasal catarrh and pharyngeal troubles, as witnessed by Dr. Beaumont in the stomach of St. Martin, when suffering with gastric catarrh, where the food by coming in contact with it by the movements of the stomach, becomes coated with the mucus and the gastric juice was as effectually excluded as if coated with rubber, and it passed into the intestines as a foreign body, and by its irritation and fermentation, caused an abnormal exhalation of gasses and a watery exudation which we term diarrhoea. It is in such cases that the subnitrate in full doses, fifteen to thirty minutes before, with pepsin during or immediately after eating, will usually in acute as well as chronic cases, effect a cure, provided that you remove the cause for this, as I term it, follicular gastritis.

Combined with tannin and laudanum, as an injection, it *at once* relieves the tenesmus of dysentery; and since I have commenced its use as mentioned, with sulphate of magnesia, ipecac and opium, I have never lost a case.

As an application in the form of a powder or ointment in the treatment of old sores, ulcers and moist eczema, it will, in most cases, act charmingly. In leucorrhœa, to cleanse the parts, it has no equal.

Asclepia Tuberosa.—King speaks of it as expectorant without stimulation, diuretic and tonic, principally used in pleurisy, pneumonia, catarrh, febrile diseases, acute rheumatism and dysentery. The "National Dispensatory," 1884, says of it: "Like many other remedies, it has been alleged to possess specific powers in the cure of particular diseases, but a comparison of the reports concerning it shows that it is one of the numerous class of vegetable products which, under certain conditions, act as emetics, and even purgatives, and more commonly as sudorifics, expectorants, carminatives and anodynes. It is useful in acute rheumatism, bronchitis, pneumonia and pleurisy so far as the relation of the nervous and circulatory systems can be so. The 'pleurisy' it is credited with relieving was most probably muscular rheumatism of the walls of the chest."

In the fall of 1852, during the prevalence of a very fatal epidemic of dysentery in Montgomery county, a man recently from North Carolina, living on one of my father's farms, came to me to know where he could find some of this weed, as his wife was almost dying with the pain in her bowels caused by "bloody-flux." One cup of a hot infusion gave almost immediate relief and impressed me, a lad of 15 years, with its great value as an agent to overcome one of the most distressing symptoms in this disease, and one which the physicians at that time seemed powerless to suppress. It is, therefore, in the tormina of dysentery, so distressing to the patient, that the fluid extract in teaspoonful doses every two hours or a

warm infusion of the fresh root acts like a charm; and with one trial few will dispense with its services to relieve this condition.

In the so-called "bilious" and other forms of colic, either alone or combined with an equal portion of dioscorea villosa and a little morphine or chloroform, it acts charmingly; often one, seldom more than two doses being necessary.

The pain consequent on acute muscular rheumatism will be relieved in from six to eight hours by its administration in drachm doses every two hours.

It is, in the severe pains (call it muscular rheumatism of the chest if you please) in pneumonia that I use it most frequently, and I assure you that when administered as before mentioned, it will almost invariably give relief in from eight to twelve hours and this condition can be maintained by ten drop doses every two hours, with such other treatment as is deemed necessary to meet the indications.

In those cases of fever of a continued type, frequently met with in young children as well as adults, which resist the usual antipyretic treatment, I have found it, in small and frequently repeated doses, to act promptly and efficiently, by a marked reduction in the temperature and pulse and a moist skin resulting in the long needed quiet sleep, thus seemingly overcoming a condition which rendered the usual antipyretic list valueless. *Asclepia tuberosa* is certainly a sudorific, anodyne, and occasionally though an idiosyncrasy an emetic.

Hillsboro, Ill., July 6, 1886.

MEDICAL PROGRESS.

LANOLIN.—In some notes on this subject DR. WALTER G. SMITH says: It is a very interesting body from more than one point of view.

1. It is a neutral fatty salt of cholesterol (a monatomic alcohol) takes the place of glycerin, which is the radical of ordinary fats.

2. Liebreich has demonstrated the wide diffusion of this cholesterol-fat throughout the animal kingdom.

3. It is not a secretion arising from sebaceous or other glands, but is a product of retrograde metamorphosis of keratin or keratin-yielding tissues.

Liebreich suggested, but was not prepared to prove, that cholesterol-fat was present in the keratin-cells, or in the granular layer of the epidermis from which the keratin-cells are derived; but Lewin (*Berl. klin. Woch.*, 1886) has since shown that its presence can be demonstrated micro-chemically in the granular layer of the skin by Liebermann's test (acetic anhydride and sulphuric acid).

4. Lanolin commends itself, pharmaceutically, as a basis for ointments.

Shortly after reading Liebreich's paper, I obtained some lanolin from Mr. Martindale, and began to prescribe it. Within the last two and a half months, I have employed it frequently (over seventy times), and feel assured that it possesses properties which deserve attention from all practitioners. These properties are the following:

a. It is capable of absorbing and intimately blending with large amounts of water, standing thus in marked contrast to popular notions of the mutual relations of water and fats. The lanolin of commerce is a combination of neutral cholesterin-fat with about 30 per cent. of water.

b. It is neutral to test-paper, is not liable to rancidity, and is not easily saponified by alkalies.

c. It is miscible with glycerin, unlike other fats.

d. It rapidly, and in a remarkable degree, possesses the power of penetrating the epidermis.

e. Hence lanolin greatly facilitates the absorption through the skin of drugs mixed with it. So marked in this, that, with poisonous drugs, such as the toxic alkaloids, less (about half) than the usual proportion should be prescribed in ointments. The vaselins and paraffins hinder, rather than favor, the passage of drugs into the skin.

I will now briefly mention two or three cases in illustration of the uses of lanolin.

Eczema.—Captain —, a patient of Dr. Gilbert Lynch, consulted me while on a visit in Dublin. He was a corpulent man, with varicose veins in both legs, and was much troubled by an angry outbreak of eczema rubrum on the legs, on and off for two years. For this he had had the best advice in London, but without very satisfactory results. When I saw him the leg was weeping, fiery red, and intolerably itchy. The following ointment was prescribed. Lanolini 3xij; adipis benz. 3j; liq. plumbi subacet. fort. m xv; acidi carbol. 3ss; olei lavand. m v.

Speedy improvement ensued; the itching was calmed; he was able to walk about in comfort, and in about three weeks was practically cured. Ethereal solution of nitrate of silver (20 gr. to one oz.) was twice applied.

Psoriasis.—Miss G., aged 25, was sent up to me from Doneraile, County Cork. For fifteen years she had been subject to psoriasis, here and there; and in January, 1886, the disease suddenly developed into an extensive eruption over the face, chest, back and limbs; in fact, no part of the body was spared. She was covered from head to foot with small circular scaly patches.

I first prescribed a lotion of soft soap, spirit, and carbolic acid, which smarted her. A few days afterwards, this lotion was applied to one limb and ointment to the opposite limb (lanolin and lard, including pyrogallic acid 40 grains, and salicylic acid 20 grains, respectively, to the ounce). This ointment caused no irritation, and exercised a more favorable influence on the eruption. Progress, however, being rather slow, I substituted for the above ointment a lanolin and chrysarobin ointment (20 grains to one ounce). This produced speedy and marked improvement. In a week there was a striking change for the better, and in a fortnight all infiltration and scabiness had vanished, and no trace of the eruption remained, except some brown pigmentary stains.

White precipitate ointment was used on the face, and with good effect. Arsenic was given internally.

Rheumatic Exudation.—Miss F. was attacked, four years ago, with stiffness and pain in the back of the neck. This gradually became worse, and for some

months, she suffered acute pain in the neck, especially upon movement. The head drooped down on the chest, she could not sit at table with comfort, and her life was becoming miserable. On each side of the cervical spine, especially the left, there was an indurated ridge of thickening, apparently in and between the muscles, and very tender to touch. She was given iodide of potassium and chloride of calcium internally, and was directed to rub in gently, but thoroughly, an ointment of lanolin and lard, containing 15 grains of iodide of potassium, 20 grains of iodoform, and three grains of hydrochlorate of morphine to the ounce. Improvement was soon apparent, and steadily continued; and, in about three weeks, she could elevate and rotate the head freely, and with little pain, and the hard infiltration at the nape had greatly diminished. The degree of pliancy conferred on the skin was remarkable, and the effect of the ointment in alleviating the local discomfort was unquestionable. Hitherto, I had found little reason for faith in the efficacy of iodide of potassium applied externally.

I have also used lanolin in acne, and in some other affections; and, speaking generally, can confirm the statement of Professor Liebreich and Dr. Lassar (based on over 400 cases), that it does not cause irritation of the skin. It is true that some cases of eczema were none the better, perhaps even aggravated, after the use of a lanolin-ointment; but similar experience is not uncommon with divers modes of treatment in obstinate cases of this fickle disease, and lanolin is no cutaneous panacea. In ringworm of the head, I have not had sufficient time to judge fairly of its effects.

With chapped hands, its effects are extremely satisfactory, and several bad cases occurring among my friends during the recent severe weather were cured by a single inunction of lanolin. For this purpose, perhaps, simple lanolin is the best to use, as it is rapidly incorporated into the skin. For general use, its stickiness should be counteracted by admixture with one-eighth or one-fourth of another fat (lard, castor-oil, etc.). A few minims of oil of lavender, or oil of eucalyptus, will communicate an agreeable odor to the ointment.—*British Medical Journal*, July 12, 1886.

CONTINUOUS RECTAL ALIMENTATION.—DR. DUNCAN J. MCKENZIE says that the labors of Sir William Roberts, of Manchester, and others, in the field of artificial alimentation, have undoubtedly made the prospect of supporting life by rectal feeding more bright. There is, however, this difficulty in intermittent administration, that an enema, however small, is apt to cause a desire for defecation.

It has occurred to me that we may imitate the process of nature more closely by the gradual passage of a fluid from an artificial cavity, in which its digestion takes place, into the rectum for absorption. In this way, supply keeps pace with absorption, and the bowel is not loaded.

The way in which I proceed is as follows: A piece of celluloid catheter (No. 5) is passed into the anus for about two inches; if passed too far, there is a risk of its being closed by the folds of gut. When

once introduced, the sphincter closes upon it, and its presence is hardly felt by the patient; and the celluloid, rigid when introduced, becomes rather softer from the heat of the body. Previously to introduction, this piece of catheter is passed through a thick piece of India-rubber, perforated so as to grasp the catheter tightly. To the four corners of the India-rubber are attached tapes, which are tied, two in front and two behind, to a band round the loins. This India-rubber is passed close up to the anus, and the tapes are tied as tight as convenient. Over the outer end of the catheter is passed one end of a piece of fine India-rubber tubing, such as is used for babies' feeding-bottles. The piece of tubing should be about two yards long, and its other end slipped over a metal tube let in close to the bottom of a moderately tall narrow vessel, made of tin or other material, and capable of holding a pint of fluid. To increase steadiness, the bottom is leaded on the outside. The only other apparatus required, are a milk-strainer to fit the mouth of the vessel, a table about the same height as the bed on which the patient lies, a few small boxes, or some suitable support by which the elevation can be varied, and an ordinary tea-cosy.

A pint of milk is warmed to a temperature suitable for pancreatic digestion; a little bicarbonate of soda, and a proper quantity of some preparation of pancreas, two teaspoonfuls in the case of Mr. Benger's liquor pancreaticus, are added, and it is allowed to stand in a moderately warm place for half an hour. It is then passed through the strainer into the vessel mentioned above. I find that after standing half an hour, the milk leaves little or no curd upon the strainer, and when strained, readily passes through the tubes. If the curdling of the milk, by the pancreatic extract, give trouble, it may be prevented by previously adding one-fourth of its bulk of water to the milk (Roberts).

The milk, having been put into the vessel, which acts as the artificial stomach, it is raised from 2 to 2½ feet above the level of the patient's bed, the height being altered according to the rapidity with which the milk runs through the tube. The vessel is then covered with the cosy to keep it warm, and if necessary, a heated plate may be put under it at intervals. The pint of milk should run into the rectum in about three hours, which time fairly corresponds to the average digestion-period of pancreatised milk. If a desire for defæcation be felt, the flow should be made slower, or the apparatus entirely removed for a time.

When the milk has all run out, the apparatus is removed, some clean water passed through the tubes, and the patient allowed to rest for a time before re-introduction.

In this way, a patient of mine, suffering from cancer of the stomach, in whom the colon was obstructed at the junction of the transverse with the descending portions, received an average of three pints of milk per day for a month, with an average daily evacuation of about a pint, consisting chiefly of curd; his nutrition was fairly kept up until vomiting of blood, mucus, and faecal matter became excessive; and, after death, the whole descending colon was found well nourished and containing condensed milk. His evacuations

generally took place from two to eight or nine hours after milk had been administered, care being taken not to give any when the rectum felt irritable.—*British Medical Journal*, June 19, 1886.

CIRCUMCISION UNDER COCAINE.—Various experiments have been made with solutions of the hydrochlorate of cocaine with the object of producing such local anæsthesia of the prepuce as would result in a painless circumcision. The results of quite a number of such efforts, while greatly lessening the pain of circumcision, have not been entirely satisfactory. In the last two operations, however, which Dr. F. N. OTIS (*N. Y. Med. Journ.*, May 8, 1886), reports having done by a new procedure, the first was entirely painless; in the second there was only slight sensitiveness in putting in the last few stitches.

The plan pursued was as follows: Retracting the prepuce, 3 or 4 drops of a 6 per cent. solution of hydrochlorate of cocaine were injected with a fine hypodermic needle into the internal layer of the prepuce about half an inch from its attachment at the base of the glans penis. This was done so superficially that, as the needle was withdrawn, a little bleb was formed nearly half an inch in length. Waiting for half a minute, the needle was again introduced at the opposite side of the bleb, and it slid in painlessly for another half-inch in the line of the circumference of the penis. In this manner blebs were made until the cervix was completely encircled by them.

The prepuce was then drawn forward, and, by a simple procedure, another line of blebs was made to encircle the external preputial layer at the point elected for the incision. This was intended to be directly opposite the line of injection of the internal layer. The prepuce was then advanced so that the line of injection cleared the end of the glans, at which point it was compressed by a clamp, and excised without the least pain.

The clamp was then removed, the internal layer of the prepuce was slit up, turned back, trimmed with the scissors, and attached to the incised edge of the external layer by continuous suture, comprising about twenty stitches. Not the least pain was experienced in the operation except that caused by the first introduction of the needle in the internal layer, and the same in the external layer. 20 drops of the 6 per cent. solution were used in this case. In the second 25 drops of a 4 per cent. solution were injected. The chief embarrassment of the operation consisted in the fixation of the delicate tissues so as to introduce the needle with accuracy, superficially, and to a sufficient extent. An ordinary mouse-tooth forceps answers very well, but a forceps in which the needle can ride would be an advantage.—*Therapeutic Gazette*, June 15, 1886.

BACTERIA-THERAPY.—DR. FRAS. TROUP has recently satisfied himself that a sputum which has putrified for fourteen months still contains tubercle bacilli, which are capable of reproducing their kind; and therefore, the good results of spraying with *bacterium termo* must be attributable to some other cause.—*Brit. Med. Journal*, June 19, 1885.

CHICAGO, ILLINOIS.

SATURDAY, JULY 31, 1886.

MEDICINE IN 1936.

As is very well known, the late Dr. Austin Flint was to read the Address in Medicine before the British Medical Association at its annual meeting in August, 1886. After his death the manuscript of the Address was found among his papers, and it has now been printed by Appleton, under the supervision of Dr. Austin Flint, precisely as it was written by his father. It is entitled "Medicine of the Future." This, so far as is known, was the last literary work of the great master, and though he had several months in which to prepare it before it was to be delivered, in this case, as with all his other work, he made his preparations in ample time.

While there is no discussion in the Address of any new method of treating disease, or of any particular subject in medicine, many valuable suggestions may be found in it, and much that will give rise to serious thought. "To look forward, as well as backward, is both interesting and useful. If our retrospections extend over half a century, it is worth while to inquire, How will the present appear in a retrospective view at the end of the next fifty years?" It is in the spirit of this inquiry that Dr. Flint offers some thoughts on the medicine of the future. He assumes that medicine, as it is to-day, will not remain stationary; the past history of medicine shows progress, and it is only natural to conclude that it will continue to advance. The past gives an assurance of progressively increasing security from the outbreak as well as from the effects of disease; and we may conclude that the future will do much more in those directions. As with all sciences, the advances in medicine have been by means of discoveries, improvements and added facts which have marked epochs in its history.

In medicine, as in other sciences, there are still many worlds to be conquered, many mines to be explored, and many virgin fields to be turned up and cultivated.

The fifty years preceding 1836 were marked by the discovery of auscultation by Laënnec, the laying of the foundation of renal pathology by Bright; and Bichat, Magendie and Bell created general anatomy and added to the knowledge of the nervous system; Poiseuille conceived the idea of a sphygmograph in 1829, though it was not until the present half century that the lever principle was applied to this instrument, which, in spite of its general neglect at present, is destined to great service in the future. It was in 1831, just five years before the beginning of this half century, that Leuchs showed the diastatic action of the saliva. Carminati and Prout (1785 and 1824) found that the gastric juice was acid, and that the gastric juice contained hydrochloric acid; and it was in the first year of this half century that Sprott and Boyd discovered the gastric glands. In the same year Schwann isolated pepsin, while two years before Eberle prepared artificial gastric juice. It was in the first year of the last half century that Purkinje and Pappenheim referred to the fat-splitting action of the pancreatic juice, and its diastatic action, its emulsifying power, and its tryptic action were soon discovered by Valentin, Eberle and Bernard. It may seem remarkable that nothing, comparatively speaking, was known of the liver until 1838. It is within this half century that the reflex system of nerves was discovered and the separate functions of the different portions of the spinal cord; the recognition of the self-limitation of certain diseases; that histology has been created by the microscope; that certain cerebral functions have been localized, and that cerebral surgery has been put on a new plane; that ovariectomy has been revived and brought to its present state of perfection; that anæsthesia has been discovered; that the clinical use of the thermometer has been revived; and that the bacterial origin of diseases has been revealed.

To what department of medicine must we look for the most brilliant results in the next fifty years? Most probably to that of physiological chemistry, which carries its investigations beyond the bounds of microscopical observation. The application of the microscope to the study of healthy and diseased tissues has given a wonderful impulse to medicine, and it is entirely probable that much more will be done as that instrument is improved in its construction, and as further progress is made in the use of staining agents. It is probable also that the use of the spectroscopic will be greater. But it may be said that the probabilities and

possibilities of physiological chemistry are limitless. The work begun by Liebig has only just begun. Histology may disclose agents, but to physiological chemistry we must look for the agencies. It is in this field that we must work if we would find out how secretions, excretions, nutrition, growth and certain morbid products are brought about. The microscope has revealed the existence of micro-organisms, but physiological chemistry must tell us regarding the toxic products of these microscopic agents, and how they give rise to disease. So also in regard to the action of drugs. It is not an explanation, but a statement of a fact to say that a certain drug acts upon a particular tissue, or that it causes a particular effect. Chemistry must tell us how and why this drug acts in a certain manner. These views have been repeatedly advanced, and the supreme importance of chemistry as a corner-stone of medicine has been advocated in *THE JOURNAL* for some time past, and it is with no little pleasure that we now record the endorsement of the departed master.

Fifty years ago that man would have been thought an idle dreamer who had said that within the memory of some then living it would be possible to converse with a person hundreds of miles away, or that a fibroid tumor of the uterus would be melted away by the electric current, or who mentioned such words as phonograph, microphone, or cablegram. These marvelous developments of electricity, says Dr. Flint, have not added much as yet to our knowledge of the normal and abnormal actions taking place within the human body, but much is to be expected from this source in the future. "It seems to me certain that the principle of the telephone will, by and by, be applied to intra-thoracic respiratory and heart-sounds, so that they will be transmitted to the ear with more distinctness than they now are by the binaural stethoscope. The healthy and morbid sounds will then be so easily discovered as to render the physical diagnosis of pulmonary affections in all cases a very simple problem. More than this, the clinical teacher may be able to demonstrate auscultatory signs to a class of medical students comfortably seated in the lecture room or hospital amphitheatre." The same may be said in regard to the physical diagnosis of heart sounds. "I will go further, and say that intrathoracic sounds may be transmitted from the patient to the physician, no matter how distant one may be from the other. Again, and still further, the sounds from the chest of a patient may be phonographically, transported never so far, and made available after an indefinite period." "Who knows," said Robert Hook, in 1705, "but that

one may discover the works performed in the several offices and shops of a man's body by the sounds they make, and thereby discover what instrument or engine is out of order!" Surely Hook might claim, were he now living, that his prophecy of one hundred and eighty-one years ago had been fulfilled by Laennec. But who will say that his prophecy has been completely fulfilled? Who will attempt to predict the limits of auscultation when the foot-fall of the fly has been heard through the microphone?

Again, the sum of our knowledge of the natural history of disease has been vastly increased in the last fifty years. Half a century ago the sharp line between self-limited and other diseases had not been drawn, but we can scarcely estimate the influence of our present knowledge of the natural history of diseases upon therapeutics. There is still much to be done in this great field. "With the now prevailing views, it seems a surprising statement that phthisis pulmonalis may be self-limited and end in recovery purely from an intrinsic tendency; yet, I venture the assertion that the correctness of the statement has been substantiated, and that before many years elapse it will be generally acknowledged to be a clinical fact. How important is this fact in judging of the agency of medicinal, climatic, and hygienic measures in the treatment of this disease!"

Dr. Flint predicts that venesection, "the lost art in surgery," will be revived. It may be questioned, however, if bloodletting be really a lost art. It is not so frequently resorted to as formerly, but we know more of its dangers than did medical men fifty and one hundred years ago. The giving of calomel in ten grain doses, and more, may be said to be a lost art in the same way as indiscriminate venesection, or as the use of small doses of quinine in malarial fever. It is a mistake to suppose that venesection has been abandoned; it is a much more serious mistake to resort to it when not indicated. We should take advantage of its prompt and efficient effect in certain conditions of disease; and we must "observe a proper conservatism as regards its potency for harm as well as good." It is quite certain that its dangers and evils were formerly overlooked, and that they are now somewhat exaggerated. It should be remembered that "a remedial agent can have but little value if it be not capable of acting injuriously as well as usefully. In the ability to employ potential agencies so judiciously as to secure their good and avoid their evil effects, lies the secret of true success in the practice of medicine."

The bacterial origin of disease is intimately connected with preventive medicine. We may be said

to be just awakening to the dawn of a great revolution in medicine, and in this revolution bacteriology and preventive medicine will play a most important part. Our lack of information regarding the etiology of diseases is deplorable. This field will yield a rich harvest to patient workers, and as it is tilled preventive medicine will gradually claim its proper recognition and importance. The time has past when one may say that a disease has a spontaneous origin. One point which Dr. Flint makes is, assuming the truth of the parasitic origin of any one of the infectious diseases, that it is a logical inference that this truth is applicable to the other diseases of that class; and furthermore, the discovery of a specific micro-organism as the cause of a disease, places it in the list of infectious diseases, although it may not have been considered as belonging to the class. And if this reasoning be correct it is only a question of time when specific organisms will be discovered for all the infectious diseases. And what will be the influence of these discoveries upon medicine in the future? "Having acquired knowledge of the natural history of the different species of parasitic organisms, a great practical object is to find means for their destruction within the body." We can scarcely doubt that this will be done. Though the parasite of malarial fever has not yet been certainly described, the parasitocides of the disease were discovered long ago. It is possible that parasitocides in cases of other infectious diseases may be discovered before the parasite, or *vice versa*. There may be very many difficulties in the way, but as each one is overcome the others become easier. But we have thus indicated only a portion of this vast field: when the parasite is discovered we must find some means for preventing its growth and terminating its existence outside the body, and for effectually excluding it from the body; and it is here that preventive medicine claims its place. It is very probable that the work now being done in the way of inoculating with attenuated virus will at some time put us in the way of forestalling other diseases than small-pox.

And besides all this there are glands within the human body the functions and uses of which are but little known, and whose pathology is an unexplored field. The spleen, the gastric glands, the glands of Lieberkühn, the lymphatic glands, the thyroid gland and the supra-renal capsules, and even the liver, are vast and fruitful fields for future clinical, physiological and pathological research.

Space is wanting to follow the address in the remarks on the future of medical literature, on the future of the profession, on future medical teaching,

and on specialism. The only regret on laying the little volume aside is that its great author has finished his work.

THE BEARING OF THE PRESENCE OF ALBUMIN OR SUGAR IN URINE ON LIFE INSURANCE.

It has come to be a well-known fact that albumin is often detected as a temporary constituent of urine in persons who present no other evidence of ill health; and the same may be said in regard to the presence of sugar. To medical examiners and medical supervisors for life insurance companies such cases give much embarrassment. And to arrive at conclusions just both to the applicant and the insurance company it is necessary not only to repeat the chemical tests on urine passed at different times in the day and at intervals of several days, but to add examinations with the microscope. The following suggestions taken from a letter written by one of the most experienced Medical Directors of an important life insurance company in Philadelphia, are worthy of note:

"*Dear Doctor*.:—In reply to your favor in regard to our action in cases where albumin is found in the urine, I may state that the following is our custom: Where the applicant is (1) a young person of good habits, (2) good family record and (3) physique, and the amount of (4) albumin is small and (5) specific gravity normal, we usually request the examiner to make several examinations of the urine at such times as he sees fit, to find whether the presence of albumin was accidental or not. In such cases, if it is proved that it is not a constant condition and due to renal disease, we will probably issue a policy for a small amount. If a large amount of insurance is requested we would require a microscopical examination of the urine under such circumstances.

"If the applicant is (1) past middle age, at the time when degenerative process begins, (2) has been a free liver or accustomed to luxurious habits or has undergone mental strain, (3) or has been overworked and closely confined to business, (4) with irregular hours, etc., the presence of the smallest amount of albumin in the urine we consider an absolute impediment to life insurance.

Possibly science may teach that such persons, with great care, will live as long as any one, and therefore the *family physician* can give a favorable prognosis, but an insurance company which is obliged to take *only safe risks* cannot place money on such an individual.

"The same action is taken when sugar is found."

DEATH OF DR. R. C. HAMILL.

Died at his residence in Chicago, on July 21, 1886, Dr. R. C. Hamill, one of the oldest and most highly respected practitioners of medicine in the city. Although 78 years of age, he had continued to attend to his ordinary professional duties more or less, until near his death.

For many years he had been an active member of the Chicago Medical Society, the Illinois State Medical Society, and the American Medical Association, to the *Transactions* of all of which he had made valuable contributions. He was a faithful, generous, and skilful general practitioner, commanding the full confidence of a wide circle of patrons. As a citizen, he was universally respected, for he was a man of perfect integrity whose highest enjoyment was derived from relieving human suffering and in promoting the best interests of the whole community.

AN EXCELLENT EXAMPLE.

We are informed by the Treasurer of the Ninth International Medical Congress that he has received, for the Congress, the sum of \$500, donated by the Michigan State Medical Society at its recent annual meeting. The Executive Committee of the Congress must necessarily expend a large sum of money in printing and distributing circulars, and in perfecting all the arrangements preliminary to the actual assembling of the Congress. The liberal action of the Michigan State Society is timely and appropriate. It is very desirable that the good example presented should be speedily followed by the State Medical Societies of other States, and also by the leading societies in our most populous cities and counties.

COLDWATER SANITARY CONVENTION.—The Sanitary Convention previously called for Sept. 23 and 24 in Coldwater, Michigan, will be held on Thursday and Friday, Sept. 9 and 10, 1886, instead of the first named dates.

SOCIETY PROCEEDINGS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Forty-Sixth Regular Meeting, Friday Evening, April 23, 1886.

THE PRESIDENT, DANIEL T. NELSON, M.D.,
IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

(Concluded from page 107.)

DR. JOHN BARTLETT made remarks upon, (with the exhibition of specimens of)

(1)—A CASE OF DERMOID CYST COMPLICATING LABOR.

(2)—A CASE OF PLACENTA PRÆVIA IN WHICH
THE PLACENTA WAS EXPANDED OVER
THE ENTIRE OVUM.

Dr. Bartlett said: "I have recently seen two interesting cases of labor, and I wish to present a specimen obtained at each of these, to the Society. The first was a case in which I was called to assist Dr. John S. Clark. The patient, a primipara, about 30 years old, had been in labor under the care of a midwife about twenty-four hours. The head was making no progress, and exhaustion was approaching; about one ounce of fluid extract of ergot had been given. Dr. Clark found the head lying with the antero-posterior diameter corresponding with the conjugate, the parietal eminences had passed the brim. He applied an old style, high curve, Bedford's forceps, but found his efforts unavailing in causing the head to advance. Dr. Bartlett then attached his direct traction handle, and descent of the head was effected. After delivery of the head there was difficulty in delivering the shoulders. When an effort at extrusion was made, there appeared in the perineal region, between the vulva and tuberosity of the ischium, a jutting outward of the tissues in the form of a tumor. It seemed as if an obstructing body was wedged in front of the shoulders. Counter pressure was made upon the protrusion, and the delivery was completed. Following the child, came a tumor of the shape and size of a large pear, presenting at the small extremity a pedicle. It was a thin dermoid cyst containing a mass of fatty substance, embedding numberless long intertwining hairs. The tumor could not be felt during labor, and a careful inspection showed that it had not been attached to the child. It was probably attached to the uterine surface, resting between the head and the shoulders. Possibly it was the cause of the dystocia in diverting the head from an oblique diameter of the brim. Depression of the vital powers with high fever set in soon after delivery, resulting in death within four days. Dr. Clark's examinations, *post partum*, detected no injuries beyond laceration of the perineum. The child was still-born.

The second case was one of placenta prævia. Mrs. N. had several children, and within eighteen months past, two miscarriages. In January last, when she was nearly four months advanced in pregnancy, I was called because of serious hæmorrhage. The uterus presented to the touch nothing peculiar, there was none of that extra development of the lower segment of the organ which is supposed by some to indicate placenta prævia. The tampon was applied, opiates given, rest enjoined, and the bleeding ceased. At four and one-half months the hæmorrhage recurred. Under treatment, the bleeding was in some measure controlled. For the two following months it was continuous, generally moderate, occasionally quite severe, at all times, as she declared, four-fold greater than the flow of menstruation. I then deemed it best at six and one-half months to induce labor, but Dr. John S. Clark, in consideration of the probable non-viability of the child, advised further delay. The flow, however, was so great that the tampon was ap-

plied, and in forty-eight hours thereafter labor began. Upon removing the plug, the os was found thin, softened, and three-quarters of an inch in diameter. At about the fourth hour of labor, the os rather suddenly enlarged to a diameter of one and a half inches, and the hæmorrhage became profuse. The half hand was introduced into the vagina, and the placenta stripped off over an area, the radius of which was three-fourths the length of the middle finger. With the bullet forceps, used by me with advantage in such cases, the membranes were torn, and the opening so made was freely enlarged by the finger. Hæmorrhage immediately ceased, and labor became more active, so that in the course of an hour the child was delivered, breech first. Several inspirations were made by the foetus, a fact of interest, in view of the peculiarities of the placenta, which I here present. In order to display the specimen to better advantage, I have filled the cavity of the membranes with horse hair and sewed up the aperture. It will be observed that the main body of the placenta, the normal placental mass, is not prævia, but attached near the fundus, and that the rare anomaly is here presented of a continuous placental tissue spreading over the entire ovum. Observe that the extra, adventitious portion, continuous with the normal placental edges, and everywhere enveloping the membranes, is comparatively thin; in the present state not thicker than one-eighth or three-sixteenths of an inch.

DR. W. H. BYFORD spoke of a specimen he exhibited some time ago at the Chicago Medical Society—a dermoid cyst which was expelled from the vagina. It was sent to him by Dr. White of Bloomington, who said the tumor was situated in the anterior wall of the vagina, and as the child was delivered the pressure of its head pushed the tumor out before it. He thought that in the case under discussion the tumor may have been developed in the vaginal walls. The localities of these growths are not uniform and we find dermoid cysts situated in the vaginal walls. Bartlett said in answer to a question from Dr. Byford that the existence of the cyst was not discovered before but during labor; that it was beyond the head and may have been an ovarian tumor; it was not outside the vagina, but between the head and shoulders. Dr. Byford thought it almost certainly a dermoid tumor of the vagina. He thought that these cases are almost always found in old or multiparous patients.

With reference to Dr. Bartlett's second case, he asked if the hæmorrhage ceased before rupturing the membranes, or if the whole operation was done at once. Barnes claims that if the membranes are separated over the cervical zone the hæmorrhage will stop; that there will be sufficient retraction of the cervical zone to close up the mouths of the vessels. He thought it a point of interest to know whether or not that would have stopped the hæmorrhage, and whether it would not have been sufficient. He thought in that case one is not called upon to leave the membranes intact.

DR. DELASKIE MILLER said that the effect of endometritis is usually to increase the area of the development of the placenta, and he had not infre-

quently seen cases of placenta of the usual size, on which projections appeared in different parts in the interior of the uterus, partially connected or entirely disconnected. He asked whether a case of endometritis might not allow the villi of the chorion to form these *placenta succenturiata*. He was inclined to think that condition would encourage it. Another fact in the history of the case that would perhaps justify this theory was the several miscarriages the patient had experienced before this pregnancy.

DR. T. D. FITCH said that in thirty-five years of practice, in which he had probably attended more than a thousand cases, he had seen but one case in which he suspected placenta prævia. He was sometimes ashamed to make the statement for fear his experience had been from lack of close observation, or inability to recognize a case, but he had seen only one, and did not know that that was really a case of placenta prævia. He did not detect it by manual examination; the symptoms were altogether subjective. It was a seven months' labor and the child lived. There was a good deal of hæmorrhage. He had no difficulty with the labor, except from the hæmorrhage, and that did not prove serious.

THE PRESIDENT asked if any one could suggest the origin of the tumor? Was it a twin or a dermoid thrown off from the foetus, or was it from the mother. He asked Dr. Bartlett if it was a part of the child, and was answered after careful examination no place was found where it might have been attached. It was perfectly loose in the vagina; probably the pedicle had been ruptured.

DR. EDWARD WARREN SAWYER thought with reference to Dr. Bartlett's second case the case had several interesting features, and the subject itself is full of interest. He referred to a conversation earlier in the evening in which Dr. Byford had said that he had been in practice many years before seeing a case of placenta prævia, and the first case he ever saw was the first of three in one night. It had happened to Dr. Sawyer to see a number of cases of placenta prævia. He had had two fatal cases, and had learned something of early diagnosis, which had been profitable to him since, and he thought of it in the obscurity of the diagnosis in Dr. Bartlett's case. He said that in one of his cases, after reading of the ease with which one could auscultate the lower segment of the uterus under these circumstances, he prolonged his stethoscope with a long flexible tube, put a cup on the end of it, and had no trouble in introducing it into the woman's vagina. He had repeatedly detected portions of the cervical attachment of the placenta by this mode of auscultation. The remark made by Dr. Byford had received some confirmation in his experience, viz.: that many cases of placenta prævia aborted early and that he believed this to be a frequent cause of early abortion. Spiegelberg says that placenta prævia is of frequent occurrence. An interesting fact in connection with Dr. Bartlett's case was the alarming amount of hæmorrhage which took place from the placental attachment away from the main part of the placenta; or in other words, there were sinuses in the cervical zone of this uterus which were covered only by the velamentous

portion of the uterus—sinuses large enough to bleed, and exsanguinate the woman. Dr. Sawyer spoke of a case to which a former pupil of his was called. A midwife summoned him at midnight to see a woman who was bleeding to death. As he entered the room she handed the doctor a cord (the child was delivered), and the placental end of the cord was a disc about as large as a butter dish. That fleshy mass had been pulled directly from the placenta and the woman was actually bleeding to death. This little mass was very thin, and he was at a loss to understand to what part of the placenta it could have been attached. He delivered the woman completely and she was saved. He found a hole through the placenta corresponding to the disc which had been pulled out; it was in the thin portion of the placenta, and the bleeding was somewhat alarming. Referring to the question that Dr. W. H. Byford asked concerning the mode of treatment advocated by Barnes, Dr. Sawyer said he was full of the idea, and the feasibility of it was accepted by him in his first reading of Barnes's work, and he tried to adopt it in practice, but he hoped no one would ever get himself into such a dilemma, as he was sure he lost his patient by that course. Theoretically you may detach enough of the placenta to save the woman from hæmorrhage. The so-called cervical zone is not to be measured by the finger; he did not think it had any definite boundaries; it might sometimes extend halfway to the fundus on one side of the uterus, and he thought the more we detach the more dangerous it may become. He felt quite confident that the poor woman who was the victim of Barnes's theory would not be dead to-day if he had adopted a more rational treatment.

There was one point in connection with the causation of placenta prævia that excited a great deal of interest in his mind. He had seen two cases strangely confirmatory of the movement of the ovum in the early days of its sojourn in the uterus. One case was also seen by the President, but he had never spoken to him of the theory of which the examination of the placenta had been the origin. Dr. Sawyer had written to several prominent obstetricians of this country, asking if they knew anything in the literature which would answer the question: Can the ovum once attached to the decidua of the uterus become detached and again attach itself to the lower part of the uterus and go on through pregnancy? In other words, can the ovum detach itself, drop from the top of the uterus to the bottom, re-attach itself in the cervical region? Many learned men replied that they had never heard of such a possibility. But Dr. Harris, of Philadelphia, hit upon this happy expression: "Rotation of the ovum." He had seen two cases in which he thought the ovum rotated in the earliest days of pregnancy; not a complete rotation, but an almost complete detachment and rolling, or rotating, downward and there attaching itself. The second case was in the practice of Dr. Doering. The subsequent examination of the placenta showed a case of partial placenta prævia. The umbilical cord springs from the margin of the placenta in both instances; and his theory was that in the first case, which was that of a young primi-

para, the placenta was fixed normally at the fundus and the cord sprang from the middle; there was a history of a sudden jar of the body when she was about three weeks pregnant; she jumped from a high wagon and immediately flowed a little, and when she came to be delivered she had a complete placenta prævia. The examination of the placenta showed that the cord was attached to one margin, showing that it had rolled down and formed a new attachment for the umbilical cord. When the placenta was at the fundus and the cord at the middle, by its rolling downward it placed the cord at the margin. He thought one of the most important causes of placenta prævia is this rotation of the ovum very early in pregnancy; a rotation may be caused by a sudden jar, and he thought the confirmation of it is in the unusual attachment of the cord.

DR. J. H. ETHERIDGE had seen one case of a woman with placenta prævia with twins. At about the fourth month the woman fell and struck the lower part of the abdomen against a washtub, she had a little hæmorrhage, and from that time till term she was always tender at that spot. Free hæmorrhage took place and he was called to see her. The woman was delivered of a mature fœtus, and of a child that was evidently arrested in development about the fourth month. The theory was that there was a partial detachment of the second placenta, the other child went on and developed regularly. The mother died in a few hours after delivery.

THE PRESIDENT wished to say a word about the theory of causation advanced by the Secretary, the idea of displacement, or rotation of the ovum after implantation. It seemed to him that there was a more important cause, and in all the cases he had personally investigated, about four, there had apparently been good reason for the theory that disease of the uterine mucous membrane, inflammatory and with an unusual pathological amount of secretion over its surface, is the cause of the implantation at the cervix instead of at the normal place, in the vicinity of the entrance to the Fallopian tube. From the quantity of the mucus the ovum glides down to the cervix and remains there, because the tissues are more healthy, perhaps. In two cases of placenta prævia that he had knowledge of pregnancy occurred some time after treatment, with a previous history of sterility, or of miscarriages, and possibly the mucous membrane nearest the cervix was in a more healthy condition than that near the Fallopian tubes, or possibly there was constriction of the internal os. It seemed to him there was good reason for the belief that if the mucous membrane at the fundus is not in a good condition to nourish the ovum and to hold it, it falls to the internal os and is there held, and there is a possible placenta prævia at full term. He wished to know if in Dr. Etheridge's case there was any previous knowledge of uterine disease? Dr. Etheridge replied that there was none; the woman was a healthy Scotch woman.

DR. ETHERIDGE asked whether placenta prævia is a common thing in animals.

DR. SAWYER replied that he had seen a mare throw off her placenta before she threw her colt, and in

fact she died without throwing the colt. He said further that he believed cervical pregnancy is generally recognized as being secondary to another thrown off from the fundus; that being the case, why not a secondary attachment or lodgment of the ovum at the lower segment of the uterus, as well as in the cervix itself. He believed the majority of authorities is against the idea of cervical pregnancy in the abstract, but he thought Dr. Bartlett considered it possible to conceive in the cervix.

THE PRESIDENT said there might be disease of the uterus there, and then comes the question whether this is the sole cause, or one of the many causes. The question had been asked whether placenta prævia is of frequent occurrence among prostitutes, women who might be supposed to be anxious not to become pregnant, and he thought it had been answered in the negative.

DR. SAWYER asked if the President's theory was correct and his observations had been confirmatory of it, how is it that Spiegelberg can say that many primiparæ, young, healthy women miscarry on account of placenta prævia.

DR. SAWYER thought that pregnancy itself was infrequent among prostitutes.

DR. H. P. NEWMAN mentioned a rare case which had lately come to his notice, namely, a complete central implantation of the placenta, in which no hæmorrhage had occurred throughout the entire pregnancy until the very last days of gestation.

Ten days prior to delivery at full term there was the first appearance of bleeding,—easily checked by assuming the recumbent posture; and it was not until five days later that the hæmorrhage became at all abundant.

Delivery took place on Tuesday, April 13th.

On the preceding Friday Dr. R. N. Hall was called, and diagnosed placenta prævia, using the tampon. I first saw the case in consultation with Dr. Hall on Tuesday morning. The repeated tamponing and use of the colpeurynter the night before, had had the effect of gradually bringing on labor pains, and softening and dilating the cervix to the diameter of nearly two inches.

A digital examination revealed nothing but a thick placental surface upon all sides, covering, as we afterward found, the entire lower segment of the uterus. By bimanual palpation we made out a shoulder presentation (left dorso-anterior), and decided on immediate delivery.

Every preparation being made to control hæmorrhage, the placenta was carefully separated from its uterine attachments upon the left side, and the right hand carried upward between the membranes and uterine walls.

When the feet were reached the sac was ruptured, podalic version performed, and the child extracted. Meanwhile Dr. Hall had followed up the evacuation of the uterus by firm bimanual pressure upon the uterus through the abdominal walls. The placenta, which was a large one, and pretty evenly distributed upon all sides, was separated from its remaining attachments, and removed as speedily as possible. The entire procedure was accomplished in less than

five minutes, and the hæmorrhage was not excessive considering the gravity of the situation.

The child was saved, and notwithstanding the amount of blood lost by the mother at and previous to delivery, she convalesced rapidly, and is now up and about. She is a strong, healthy woman of middle age, has borne seven children, and has had three miscarriages.

With the exception of rapid childbearing, a laceration of cervix, and one faulty presentation necessitating version, her former history has no particular interest.

DR. BARTLETT said, in closing the discussion, that in a paper written years ago he had expressed an opinion that placenta prævia was one of the simplest of the *errores loci* of the ovum, that the true site of the placenta, when prævia, was the cavity of the cervix, that is, below the os internum, or the so-called ring of Bandl. Dr. Bartlett took occasion to emphasize his conviction of the truth of the position taken by him in the paper referred to. In the case now before the society corroboration of his idea might be found. An ovum resting in the comparatively large cavity of the uterus would take root on the surface to which it chanced to be more nearly apposed. An ovum arrested in the much more circumscribed cavity of the neck might secure a more general, and in some rare instances, a complete attachment to surrounding uterine tissues.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, May 6, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

(Continued from page 104.)

DR. M. O'HARA reported a case of

EXTRA-UTERINE PREGNANCY WITH RUPTURE OF THE FALLOPIAN TUBE; LAPAROTOMY ON THE THIRTY-THIRD DAY; RECOVERY.

On September 25, 1885, Dr. O'Hara was called to see R. H., who had been in good health until seized, two hours previously, with severe rectal tenesmus, agonizing pains in the pelvis, pains from both flanks, and extending down the right leg and arm. From the tenesmus she thought she would have a stool, and rushed to the water-closet, but no relief following, rushed to her room and fainted; she was carried to bed, rectal injections were given by those present, but no movement followed, and opiates were given for the relief of the pain. When I saw her she was in collapse, almost pulseless, respiration shallow, extremities cold. The whole surface was bedewed with a cold death-sweat. She could not lie on her left side or back, but reclined doubled upon her right side, and would jump up occasionally with exclamations of agony. The history hastily gathered gave the following data: R. H. was 30 years of age, the mother of three healthy children, the youngest one year old; she was still nursing it. She had never been sick, and had menstruated regularly. One men-

strual period had been missed about a week before the accident, and she considered herself pregnant.

The diagnosis was internal hæmorrhage, due to rupture of the Fallopian tube at the fifth week of pregnancy. Opiates and stimulants were used. The next day Dr. Parish was called in consultation, and concurred in the diagnosis. There was still some shock, pulsation 130, feeble and irregular; respiration feeble; temperature normal; great pallor, evidently due to the loss of blood; the abdomen was moderately distended with occasional cramp-like pains; moderate tenderness, but no symptoms of peritonitis. The patient showed signs of reaction and laparotomy, though discussed, was deferred. Five days after the rupture the patient was able to bear a close examination. The abdomen was greatly distended; there was no tenderness on moderate pressure; resonance was general except in right flank, where there was moderate dulness; there was no dulness in the left iliac and lumbar region except very far back, near the kidney. There was an apparent bulging of the right flank. The vaginal surface was generally œdematous, the anterior wall of the vagina was thicker at the cervix and to the left. The cervix is moderately soft and patulous; no bulging of the posterior pouch. It was not deemed advisable to use the sound. The urine was almost black in color. Pulse 104, temperature 99°, respiration normal. Two days later a marked jaundice appeared, although occasional vomiting and purging of bile occurred. A few days later a swelling was noticed on both sides and in front of the cervix, and a bloody painless discharge, containing decidua-like fragments, escaped from the uterus, and the dulness in the right iliac region disappeared. Urination became painful and difficult. The patient felt so much better that she desired to get up.

Three weeks after the first attack a terrible flooding occurred; it lasted for an hour, and slight hæmorrhage continued afterwards. There was decidua in this discharge. At the same time the supra-pubic tenderness extended towards the right and slightly increased on the left side, extending upward as high as the umbilicus. Chills and a rise of temperature to 101°, vomiting, constant sharp cutting pains, and emaciation, with signs of softening along the crest of the ileum, and general appearances of blood-poisoning occurred, and surgical interference was strongly urged as the only means of averting death. On the thirty-third day Dr. Parish operated, and he prepared the following report of the operation:

There were present Drs. O'Hara, R. P. Harris, De F. Willard, and McElroy. I proposed to cut down directly on the tumor by an incision immediately above the outer portion of Poupart's ligament, believing that the tumor consisted of blood coagula and pus located external to the peritoneum, and that the anterior parietal peritoneum had been dissected up to such an extent that the mass could be excised and emptied without opening into the peritoneal cavity, and without incurring the possibility of objectionable fluids reaching the serous surface. I also believed that the peritoneal cavity was clean, and that there had been no general peritonitis.

The gentlemen present advocated a median incision; for purposes of exploration and in deference to their views, I first cut through the linea alba just below the umbilicus, making an incision long enough to admit two fingers. The peritoneal cavity was found empty and the peritoneum quite normal, though somewhat congested. The exploring finger showed that the mass was external to the peritoneum, and extended upward from the left half of the pelvis to a level with the umbilicus. The broad ligament had become obliterated by separation of its layers. It was not thought advisable to explore with the finger with the view of determining the condition of uterus, ovaries and tubes. The peritoneal covering of the abnormal accumulation was evidently thin and tense, so that a careful exploration as to the condition of the uterine appendages would have endangered its rupture and the probable development of general peritonitis. It would have been an easy matter to have stitched the parietal wall of the tumor to the walls of the median incision and to have then, by incision, emptied the mass of its contents. But such a procedure would have been attended with risk of leakage of the offensive fluid into the peritoneal cavity. To avoid this risk, I now made another incision along the line of original election, *i. e.*, above the outer border of Poupart's ligament, and readily reached the mass cavity without wounding the peritoneum. This incision was made long enough to admit two fingers. About one quart of blood coagula, fluid blood and pus, escaped. The fibrinous masses were removed and all attached portions were scraped off with the fingers. The curette was avoided, chiefly because of the thin upper wall. The cavity was washed out with antiseptic fluid.

The median incision was closed with sutures, and a drainage tube introduced into the mass cavity. An incision could not have been safely made through the vagina, as the intervening tissue was too thick, and its vascularity too great. The incision made admitted of more thorough emptying of the cavity.

The patient suffered no shock from the operation. There was a slight sanguinolent discharge, containing small clots, from the drainage-tube, amounting to about two ounces in twenty-four hours. Nourishment was taken fairly. The cavity left at the time of the operation held 3xxxii. In two days it had contracted to 3i, but the discharge was purulent and offensive. A bloody discharge from the uterus had continued since the operation, but was free from odor, and diminishing. The last sutures were removed five days after the operation, and ten days later the drainage-tube was replaced by a tent. Two weeks after the operation the uterine discharge had ceased, but free bleeding from the wound occurred; there had been no exertion, sneezing or coughing, to cause this hæmorrhage, which occurred about eight weeks after the last menstruation; but a week later, a bloody discharge occurred from the uterus and wound. The temperature rose to 103°. There was no pain on pressure, but there was a suspicious hard spot in the left iliac region. Twenty-four days after the operation the patient was permitted to sit up, and while cheerfully singing felt blood streaming

down her legs from the wound; clots passed also from the uterus and rectum. She felt the rectal tenesmus and pains in right lower extremity similar to those felt at the first seizure. Much blood was lost. A similar bleeding occurred three days later, and as life was endangered it was thought necessary to give ether and explore the cavity. It was found that the tissues had been dissected up by accumulated blood and pus until the cavity extended down the side and front of the uterus and communicated with the rectum at the upper end. The cavity was thoroughly scraped with a curette and was then packed with alum sponges after disinfection with Plaft's chlorides. The patient reacted well. When the wound was injected nothing came from the rectum, but an injection into the rectum came out of the wound, and there was a faecal odor about the wound. Next day the sponges were removed and muslin tampons wet with phenol sodique were introduced. The packing was changed twice each day. Discharges of offensive faecal matter and a small gall stone escaped from the wound.

On February 15, nearly four months after the operation, the patient is noted as doing uniformly well; the wound is closing; the exudation about the uterus and vagina is disappearing, and the odor and elimination of gas while dressing the wound had disappeared.

May 1. Patient has gained greatly in flesh and presents the appearance of perfect health. A very small short sinus alone remains. The communication with the bowel has closed entirely. Menstruation occurs normally and there is no bleeding at any time from the wound.

DR. PARISH made a few remarks upon the history of this case and the difficulties surrounding a diagnosis. The patient was 30 years of age and perfectly healthy. She missed one menstrual period and a week later, possibly in the fifth week of pregnancy, there were signs of internal hæmorrhage with shock. Dr. O'Hara at this time made his diagnosis, doubtless correct, of tubal pregnancy with rupture of the cyst. The patient commenced, after a few hours, to rally. Dr. Parish was called in consultation the next day; he suggested an operation to remove the cause of the trouble but did not urge it as the symptoms had ameliorated. The patient continued to improve for several days. Afterwards a tumor appeared. The first hæmorrhage being into the folds of the broad ligament and limited did not show, but as repeated hæmorrhages occurred the tumor increased, pus formed, the embryo softened, septicæmia without peritonitis was developed and then the operation was performed and was then imperatively demanded. Three months after the original shock a sudden and nearly fatal hæmorrhage occurred simultaneously from the wound, vagina and rectum. Evidently there was a tubal communication between the uterus and the wound and a large rectal fistula had formed. This fistula healed without any separate operation.

There was evidently at the beginning, a pelvic hæmatocele without peritonitis, due to a ruptured Fallopian tube. The early operation was proposed

but did not meet with approval. It was evident the hæmorrhage was extra peritoneal as it would most probably have been fatal if it had burst into the peritoneal cavity. He deprecated the expectant plan of treatment of cases of rupture of the cyst of tubal pregnancy, but in this instance the amelioration of the symptoms at the time when first seen by him led him to hesitate as to the necessity for immediate operation. The sequel showed that in this case an early laparotomy would have been of no service. The patient's recovery is complete.

DR. HARRIS heard of this case a week after its commencement and believed from what he knew of it at that time, that it would be advisable to perform the laparotomy; but subsequent developments indicated that the hæmorrhage was extra peritoneal and gradual, and there was, therefore, no immediate danger to be overcome. When, however, he saw the patient, October 28, he was satisfied that her constitutional symptoms required that an exploration of the abdominal cavity should be made, the blood cyst defined, and then that the blood should be evacuated above the left groin. This opinion being sustained in the consultation, the operation was performed accordingly.

DR. PRICE inquired if any examination of the condition of the gall-bladder and duct had been made at the time of operation. Was the jaundice due to mechanical obstruction or to the general condition?

DR. BAER at first thought an error had been committed in not operating at first, when the diagnosis was made and the tube ruptured; but the full history puts the matter in a different light, and would cause great hesitancy about rushing in in a similar case.

DR. O'HARA had made his diagnosis at the time of the accident. Operation could not have been performed then on account of the collapse, and after that passed away it did not seem called for until the time of its performance. One question has arisen in his mind from the subsequent history of the case. Would it not have been better if the wound had been packed from the time of the operation?

SÄNGER'S CÆSAREAN OPERATION.

DR. ROBERT P. HARRIS said: I desire through this Society to give publicity to the following statement, received a few days ago in a letter from Dr. Säger, of Leipzig, by which it will be seen that his method now stands unrivalled in the world, in its ability to save human life. Locally considered, the Porro operation, as performed in the Santo Caterina Hospital of Milan, Italy, has until recently far exceeded in its proportionate success all other Cæsaræan methods in any hospital or country but this; the best of all Porro successes, has now to be rated second, as compared with its younger German rival. Laparo-elytrotomy, a year ago, stood upon the same level with the Säger operation in its rate of success; but now the latter far outstrips it in the number of times it has been performed, and in its proportion of cures. According to Dr. Säger's letter, his operation, with its modifications and simplifications, has been employed twenty-five times, saving eighteen women, or seventy-two per cent., and resulting in

twenty-two children being delivered alive, or eighty-eight per cent. In these are included three fatal American cases, which, if not in an absolutely hopeless state before the operation, gave a very minimum hope of success. The European twenty-two operations saved eighteen women, or $81\frac{8}{11}$ per cent. In the Maternity Hospital of Leipzig, Dr. Sanger has operated four times, Dr. Qbermann once, and Dr. Donal once, saving all of the women and children; in but one woman was there any special trouble after the operation. Dr. Leopold, of the Dresden Maternity Hospital, has operated nine times and Dr. Korn once; the former lost one woman; all of the children were saved. Thus we have fifteen women and sixteen children saved under sixteen operations, a mortality for the former of only $6\frac{1}{4}$ per cent. Of the four deaths in Europe, two resulted from septic poisoning which existed at the time of the operation, and in the other two subjects it followed it.

Dr. Sanger has such confidence in his method from the success that has attended it in Germany, that he believes the time has come when it should be preferred to craniotomy, because of its moderate fatality, and its saving the child. We should be glad if all of the Cesarean operations of the United States should be performed after Sanger's method as simplified by Garrigues and Leopold, but we must not expect very happy results here until our accoucheurs become alive to the fact that delay in operating will make any method fatal in a large proportion of cases. In no country are the capabilities of the old Cesarean operation greater than in the United States, and in few has this form of delivery been of late more uniformly fatal. To find eighteen recoveries under it we must search backward to January, 1863, and through a record of time covering more than twenty-three years, in which period seventy-three operations have been performed, proving fatal in about seventy-five per cent. This occurred notwithstanding an established fact that a set of early operations will save seventy-five per cent. of the women, and still higher of the children, of the United States.

TAIT ON FARADIZATION.

DR. R. P. HARRIS also presented the following letter from Mr. Lawson Tait, of Birmingham, dated April 18, 1886: "I have very strong objections to the proposal to treat cases of extra-uterine pregnancy by faradization. In the first place, the diagnosis of these cases must always be haphazard; that is to say, a correct diagnosis will not be made probably more than once in three times; the result will be that all such cases will be dealt with mischief only, and I venture to predict that this treatment will be dropped, as all such treatments are, without explanation of the case, in a very short time. My greatest objection is, that supposing the fetus has passed through the stage of tubal rupture and remained alive, what right have you to murder that child? If it goes on to the full time it may be delivered alive and the woman will have a chance of recovery from the operation far greater than with the faradization treatment of destroying the child. The cases, according to my experience, which recover from the operation are about six out of seven.

"Every one who has had much experience with pelvic tumors must have seen a certain number of cases where the fetus has died between the fourth and sixth months, and where, after a prolonged course of suppuration, it comes out through the rectum, bladder, etc.; these are, of course, the cases where the tubal rupture has taken place into the broad ligament on the left side. I have seen one right-sided case going into the bladder. It of course killed the patient.

"In the whole course of my life I have only known of one case where the woman has carried an extra-uterine pregnancy for a number of years after the death of the fetus. We know with perfect certainty all about this case, and for about eighteen years she has carried, on the left side, a condensed ovum of extra-uterine pregnancy. I doubt very much if there could be found in the whole world three other such cases; whereas the number of cases who die or who have prolonged illnesses after the suppuration and discharge of the fetus is, even in my own experience, very great."

In closing his letter Mr. Tait writes: "I wish you would make this opinion of mine known on your side."

In reply I will state: 1. We do not, in this country, practice electrolysis in cases of extra-uterine pregnancy. No puncturing needles are used, and the electro-magnetic current will not endanger the life of the patient any more if the growth to be acted upon is a tumor, than if it be as presumed, an ectopic fetal cyst. The experience of seventeen years in the United States, in which no fatal result is believed to have taken place, has only tended to establish this foeticidal method as a valuable means of saving women when in great danger of death from rupture of the fetal cyst and internal hemorrhage.

2. We do not propose to act upon the fetus after it has escaped into the abdominal cavity, unless the fetus should be very small, and be easily accessible to the pole of the battery placed in the vagina. We cannot see that it is any more a murder to destroy a two or three months old fetus after it has escaped from a Fallopian tube by rupture, than while it is still in it. The chief objection lies in the fact that such an ectopic fetus will be much more likely to give trouble after its destruction than one that is securely enclosed in a sac from which the amniotic fluid shall have been absorbed. It is true that an abdominal fetus may be delivered alone at term, if permitted to live; but it is not correct to estimate the risk of such an operation as lower than faradization properly performed, for it is far higher. Primary laparotomy, as far as we know of the operation, has been fatal in fifteen out of nineteen cases.

It is not proposed in this country to operate by faradization upon fetuses of from four to six months. Dr. T. G. Thomas has, it is true, proposed to make the limit $4\frac{1}{2}$ months, but the general impression is, that foetocide is much safer immediately and remotely if done in the second and third months, when fetal ossification is very incomplete. The entrance of foetal debris into the bladder is not necessarily fatal, as in the case related by Mr. Tait, for Parry refers to nine cases, four of which recovered.

Mr. Tait appears not to be aware of the fact that cases of prolonged ectopic gestation have been comparatively numerous, as witness the following partial record.

1. Nebel reports the case of a woman of 91, who died in 1767, and in whose body a foetus was found, that she had carried fifty-five years (Campbell on extra uterine pregnancy, 1840, page 45).

2. Brandt records one of a women of 80, who died in 1858, after carrying a foetus for fifty-six years, and bore two children while it was still in her abdomen. (Ranking's abstract, 1863, vol. 1, page 216).

3. Parkhurst reports one of a women of 77, who carried a foetus fifty-two years (British and Foreign Med. Chi. Rev. 1856, vol. 1, page 271).

4. Chiari gives a case of a patient who died of pneumonia when 82, who carried an eight months foetus for fifty years (Lancet, Lond., 1876, vol. 2, page 141).

5. Conant's case was a woman of 63, who died in June, 1863, after carrying a foetus thirty-five years (New York Med. Jour., May 1865).

6. Majon found in a woman of 78 a calcareous foetus computed at three month (Cruveilhier, *Essais sur l'Anatomie Pathologique*, Paris, 1816, tome 2, page 130).

7. Mangin and Vernier found two foetuses in the body of a women of 74, which she had carried thirty-three years (Jour. de Medicine, 1786, Gaz. Méd., July 29, 1837).

8. Morand also found a three months foetus in a woman of 78; she had carried it thirty years (Mem. de l' Acad. Roy. des Sciences, 1748).

9. Kristian Grøn found a three months foetus in a woman of 49, which had been carried eighteen years (Norsk Magazin for Lægevidensk, Band xvii, Haft. 2.)

10. Johannis Ambosi (1582) reported a case of a woman of Sens, who carried a foetus twenty-eight years. (See Astruc, *Traité des Mal. des Femmes*, Paris, 1765 tome 4, page 78).

11. Campbell reports the case of a woman of 75, in whom was found a foetus that had been carried thirty years; a foetus of about two months was also found. (C. on Extra-uterine Gestation, Edin., 1840, page 55).

12. Pepper relates the case of a patient of fifty-three, married twenty-seven years, in whose body Dr. Loder found two foetuses, one carried twenty-three years (Trans. Patho. Soc., Phila. 1866, page 102.)

13. Francis Boyle removed an 8 pound foetus after the death of a woman, of Toulouse, that she had carried twenty-six years (Philos. Trans. Abrid., London, 1794, vol. 3, page 222).

14. Cruveilhier in his *Anatomie Pathologique*, gives a plate representing a calcified foetus which had been carried many years.

15. Œlinger reports the case of a woman who carried a six and one-half months foetus about fifteen years (Prog. Méd. Paris., 1884, vol. 12, page 196).

16. Johnson's case, aged 68, carried a foetus fourteen years, after which she discharged foetal remains at intervals during thirty years (Med. Times, Lond., 1872, vol. 1, page 655).

17. Leinzell in 1720 removed from the body of a

woman of 49, a foetus that she had carried for forty-six years.

18. Watkins examined a woman of 74, who died of kidney disease, Jan. 13, 1866, and removed a foetus which she had carried for forty-three years (Brit. Med. Jour., March 3, 1866).

19. Van Sweiten also records the case of a woman of Lyons who died at 68, and had carried a foetus for twenty-seven years (opus cit.).

20. Fabri, of Ravenna, found in a woman of 55, a foetus she had carried for some years. The pregnancy was her fifth, and she bore two children at later periods (Brit. Med. Jour., March 7, 1863).

Many more cases of the same character might be added to this list, some of which would go to show that an extra-uterine foetus may prove fatal by purulent disintegration and pointing after twenty years or more. Even an ectopic foetus of three months may cause perforation of the rectum and possibly a fatal issue, although this is a rare result, it will be noticed, that in three of the twenty-one cases the foetus was computed at three months, and in another, a second foetus was of two months.

DR. O'HARA exhibited a

FIBRO-CYSTIC TUMOR OF THE UTERUS

removed after death from a patient, æt. 53 years, who had carried it for over twenty years. Three years after it was first observed she applied to Dr. Atles for relief by operation; but he declared and recommended that it should be left alone. The tumor contained numerous small cysts, and measured $39\frac{1}{2}$ by 34 inches in circumference, and weighed 30 pounds. The peritoneum was $\frac{1}{4}$ inch in thickness and was of a yellowish color.

DR. PARISH remarked that the tumor had formed no adhesions with the exception of a few slight ones to the omentum, and the removal of the ovaries and tubes would have been feasible at any time. Both tubes were dilated and in a condition of hydro-salpinx. The tumor sprung from the fundus uteri; the cavity measuring only 4 inches. The tubes and ovaries had remained at their normal position in relation to the uterus, but had been elevated out of the true pelvis. The vagina had been stretched upwards, as also had been the uterine body and neck. The uterus below the fundus had diminished in size to about that of the index finger. The bladder by reason of the traction upward had lost its attachments to the uterus, and merely retained posteriorly its attachment to the vagina, ordinarily the extent of the attachment of the bladder to the uterus becomes greatly increased in large uterine fibroids. In the specimen submitted supra-vaginal amputation of the uterus with the tumor could have been effected with out separation of the bladder from any of its attachments.

It is interesting to observe the condition of bilateral hydro-salpinx some six years after the menopause. The patient died with acute symptoms of vomiting and purging of dark fluids containing probably blood extravasated through the intestinal walls. At the autopsy no indications of perforation of the intestine were apparent. The patient was able to engage in active work until a few days prior to death,

and hence the double hydro-salpinx could not have occasioned pronounced symptoms.

Dr. William Goodell read for DR. HIRAM CORSON, of Conshohocken, a paper

ON THE STATISTICS OF 3,036 CASES OF LABOR.

In the "Transactions of the Medical Society of the State of Pennsylvania" for 1863, may be found an article headed "Midwifery in the Country," in which are drawn statistics from 2,387 consecutive cases of labor, to which are now added 649 cases, making in all 3,036 cases with 3,087 children. Head presentations (vertex), 3,012; breech, including knees and feet, 58; shoulder and arm, 5; face, 12. Twins in 51 cases. Ergot was used in 139 cases in first series. Forceps were used twenty-eight times in the first 2,387 cases and thirty-one times in the last 649 cases. Version was performed twice in the last series. One primipara was 52 years of age. Puerperal convulsions in eight cases; all recovered. There was a total of 190 cases in which the children were born before the doctor arrived, and in which the mothers did well under nature's management, and were saved the fright and suffering which, if Credé had been present, would have resulted from his fears of hæmorrhage, his rush of one hand into the vagina the moment after the child was born, and the grasping, squeezing and forcing down of the womb by the other hand on the tender, sore abdomen, to say nothing of having that heavy hand pressing on a tight bandage for two hours more, in accordance with regulation orders.

In the practice of this art I have not followed the requirements of the times. I have considered labor a natural process, and that my duty consisted in awaiting the action of the patient's forces; not setting them aside and myself usurping the duties which the natural efforts would have performed without difficulty; but coming to my patient's aid only when her forces seemed inadequate to the performance of their duties.

I have learned that the forceps are used very often—many, many times oftener in proportion to number of cases than twenty years ago, and that this is done in the early part of the labor; not because nature is inadequate to the work, but because as the physician had never hurt *himself* by using the instrument and wished to get away speedily, as he had other patients who needed attention; and though the condition of the lying-in woman would well have permitted him to visit his other patients and return in time to aid her if she needed aid, still he would not do it, through fear that the child might be born in his absence or some other doctor be called in his place. The graduate of a month can never use the forceps and all the other swift, sure means of speedy delivery, without hurting his hands or spraining his back; of course the sufferings and fate of the woman were of secondary importance. Being anxious to learn all about the advances in midwifery, I attended the meeting of the American Gynecological Association in Philadelphia, a few years ago. There I heard from the mouth of more than one eminent gynecologist—men greater than midwives—"Every year I use the for-

ceps more frequently than before." There, too, I was amazed to learn, from the experience of these speakers, how common were the cases of laceration of the cervix and perineum; so numerous, indeed, that when coupled with the fact that the advocates of frequent use of the forceps were teachers of midwifery and also eminent surgeons, skilful to "repair" these lacerations, and that these repairs brought large remunerations to the surgeons, I was dazed, I knew not what to say. I could not believe it possible that the earnest gentlemen before me could have conspired to teach this rushing plan of delivery in order that lacerations should be produced, so that the business of repairing should be brisk and profitable. It was pleasant, a few months later, to hear that the eminent gynecologist Dr. Goodell attributed the great increase of lacerations to the use of the forceps, and earnestly denounced their indiscriminate employment.

In October, 1880, the *Boston Medical and Surgical Journal* contained an article by J. W. Elliott, M.D., on "Antiseptics in Gynecology," with full directions for their use in obstetrics to prevent puerperal fever by destroying poisonous germs which might be introduced by the doctor or nurse. "At the beginning of labor the patient should have a hip-bath, the hair should be shaved from the genitals, the vagina and vulva should be washed with soap and disinfected with carbolic acid. During labor every examination should be preceded by a vaginal injection of a 3 per cent. carbolic solution to prevent the examining finger carrying germs lodged at the vulva or in the vagina up to the uterus (which is about to be more or less lacerated.) After delivery the uterus and vagina should be considered as a deep and important wound which may heal by first intention, or in which the secretions may stagnate, become putrid and be absorbed." As I had never before heard of Dr. Elliott I went on in my usual way, taking no razor to shave the parts, no syringe, no carbolic acid, but let nature go on with her work, pleased to see how steadily and perfectly she accomplishes it. Dr. Corson asks, Is labor a natural process? Are antiseptic solutions, when thrown into the uterus and vagina, safe? and answers these questions from the standpoint of his own experience and by quotations from Albert H. Smith's lecture "On the Relation of Cleanliness to the Prevention of Puerperal Septicæmia;" Dr. W. O. Stillman's account of the precautions taken by Carl Braun, of Vienna, to prevent infection in the lying-in room; Dr. T. G. Thomas, of New York, a paper read before the New York Academy; Dr. George J. Harrison, in reply to Dr. Thomas; and to papers by Fritsch and Kustner, and gives his own experience in his first labor case in 1827. Dr. Corson next considers the forced delivery of the placenta, and claims the originality of the Credé method in its principal details for Professors James and De-wees, the latter saying that it had been long since recommended by Monsieur Dassé, of Paris. He criticizes the unnecessary severity of the latter part of the Credé method and much prefers the directions given by Prof. Penrose, and then details his own method, which leaves more to natural powers,

giving morphia if rigid contraction of the os occurs before the placenta comes away.

He recommends venesection to the extent of ten or twenty ounces to relax a rigidly contracted os in the first stage of labor. If this is not immediately successful he gives morphia internally. He uses ether to relax when pains are too severe.

Dr. Corson next considers the question of tying the cord. Should it be tied at all? How soon after birth should it be divided? What is gained by waiting until pulsation ceases in the cord? These are questions to which careful consideration has been given and which are fully answered. Dr. Corson does not use a binder; has not done so for twenty years. He does not think that it prevents relaxation of the uterus, but that it favors prolapse of that organ. He gives his own experience and fortifies it by that of several other physicians.

He thinks the hasty extraction of the placenta, the compression of the uterus by the hand, and the application of the binder with the avowed intention of preventing hæmorrhage, have a bad mental effect on the patient and predispose to the very trouble we are seeking to avoid. He gives several instances of mental influences in stopping hæmorrhage. He has never used hot water, vinegar, lemon or ice in the uterus for flooding, but has applied ice externally.

Puerperal convulsions, ten cases, all recovered. His treatment consists largely in free venesection, cold water poured over the head, and morphia internally. He recommends the handbook of Dr. Ezra Mechner for the successful treatment of this malady. He would also avert convulsions by bleeding before labor to relieve headaches if accompanied by congestion of the face. Of puerperal or septicæmic fever he knows nothing, having never seen it.

the tracheæ of rabbits. These rabbits wasted away and became tuberculous, which was verified on killing the animals.

On continuing their researches the authors found the same spores and the same myceliæ in the sputa of tuberculous patients taken indiscriminately. Moreover, they discovered that the sputa in which these organisms were found to be the most numerous were equally those which contained the most bacilli, and that the sputa that did not contain microspores did not either contain bacilli. They further discovered that the bacilli were only one phasis of the development of the microsporon, and that the presence of bacilli is not necessary to characterize the existence of tuberculosis. Bacillary phthisis must, therefore, be considered as being only one of the forms of microsporic phthisis a great deal more generalized. These researches are susceptible of a great number of applications relating to the prophylaxis of tuberculosis. Pityriasis versicolor is frequent in debilitated tuberculous patients, it is often the cause of intestinal tuberculosis. These researches also concord with the opinion of those who think that the question of the soil dominates the question of the bacilli.

About a month ago, Dr. Bouchard, Professor of Pathology and General Therapeutics at the Paris Faculty of Medicine, read a paper at the Academy of Sciences in which he endeavored to show that the toxicity of the urine while a person was awake differed in quality and in intensity from that of a person during sleep. He then explained that these differences did not depend on the nature of the food nor upon the hours of meals, and that they are not in relation with the quantity of potash eliminated. For, wishing to complete his demonstration and to determine some other circumstances which, in a physiological state, increase or diminish the toxicity of the urine, Dr. Bouchard instituted a series of experiments permitting him to study the variations of the toxicity of the urine at the different hours of the day, without these differences being, in any way, imputable to the food taken. With this view, the day of twenty-four hours being divided into three periods of eight hours, he got the subject to take, at the commencement of each period, a repast always identically the same in the nature and in the weight of the food and of the drink. These experiments showed that the total amount of the urine during these three periods, viz.: sleep, the hours of being awake in the morning and those of the evening, which may be indicated, on an average, by the numbers 3, 7, 5. The augmentation of the production and of the elimination commences at the moment that the subject falls asleep, the diminution of the elimination commences in the middle of the period of wakefulness.

To ascertain the effects produced by abstinence on this toxicity, Dr. Bouchard went through another series of experiments which formed the subject of another paper which he read at a subsequent meeting of the Academy of Sciences. The author states that he suppressed the repast at the commencement of one of the periods of sleep, and he compared the total toxicity of the urine secreted during that period with that secreted during the same period, and in

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Mycotic Nature of Tuberculosis, and the Parasitic Evolution of the Furfuraceous Microspore—Toxicity of Urine Different in Waking and Sleeping Hours—Toxicity of Febrile Urine.

At a recent meeting of the Academy of Medicine, Dr. Duguet read a note on some researches that he had made in conjunction with Dr. Héricourt, on the mycotic nature of tuberculosis and the parasitic evolution of the furfuraceous microsporon. These authors noticed the existence of pityriasis versicolor on the chest and abdomen of patients who died tuberculous. At the post-mortem examination the lungs were found to contain spores, myceliæ and granulations of the furfuraceous microsporon, which led the authors to conclude that there existed a form of pulmonary tuberculosis which bears a relation to pityriasis. Experiments with the cultures of the microspores of the skin and those of the lungs produced results absolutely comparable. On several occasions insufflations of the pityriasic scurf were practised in

which he allowed the regular ration. He arrived at a result which at first sight seemed paradoxical, inasmuch as the abstinence increased by half the toxicity of the urine. This fact was explained as follows: A person reduced to live at the expense of his own substance destroys with greater difficulty and more incompletely living matter; whereas in the conditions of normal alimentation, he burns more easily and more completely the circulating material. The question is asked, what becomes of this toxicity under the influence of a day's corporal exercise of great activity, out in the country, and in the open air? Dr. Bouchard ascertained that it diminishes about one-third.

The author concluded his paper with the statement that in these physiological conditions, viz.: normal alimentation, abstinence, sleep, wakefulness during rest, wakefulness during muscular activity, the variations of toxicity appear to depend particularly on the more or less greater intensity of oxidation.

In connection with the subject of the toxicity of the urine in physiological conditions, I may here make a note of a paper read by M. Felz on experiments performed by him to ascertain the toxic power of febrile urine. The experiments were performed with human urine of subjects suffering from typhoid fever, scarlet fever, acute tuberculosis, pneumonia, and acute articular rheumatism, which the experimenter injected into the venous blood of dogs. The results obtained were as follows: The so-called uræmic accidents, from the first efforts of elimination followed or not by effects indicating nervous, convulsive, toxic or clonic phenomena, leading always to coma and nearly always to death, are manifested much more rapidly than when normal urine is employed. These phenomena are produced with urine in doses far inferior to those which would have been necessary if the experiments were performed with normal urine. The doses of intoxication are two-thirds or half inferior to the doses of intoxication of normal urine, and correspond to the volume of urine secreted by the dog in twenty-four hours at the minimum, or forty-eight hours at the maximum. The author adds that the toxic power of febrile urine is far from obeying the law of proportionality of densities. He found that there existed in pathological febrile urine agents of toxicity which are not found in normal urine, or which are represented in the latter only by quantities relatively very feeble.

A. B.

DOMESTIC CORRESPONDENCE

CREMATION.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Your editorial explanation (page 98, July 24, 1886), as to the present status of the subject of *Cremation* before the American Medical Association, is certainly correct. Dr. Keller's resolution, as cited, was thoroughly discussed in the Section of State Medicine and proved too extreme, at that time, for the small number of Sanitarians present at the discussion. I offered a resolution to the effect "That

Cremation was the most certain and feasible method of preventing possible infection from dead bodies." This resolution was the direct conclusion from the article I had read before the Section under the title of, "Purified as by Fire." The final outcome of the discussion was that a committee (as you state) was appointed to investigate the subject still further, and report to the Association next year. The weakest point in the logic of such a conclusive resolution as Dr. Keller's seems to be—Have we sufficient facts to prove *the infective power of dead bodies, and, the poisonous influence of neighboring graveyards.*

As a member of the Committee I would be pleased to receive information from any member of the American Medical Association, as to any such facts within their own knowledge. Respectfully

G. S. FRANKLIN, M.D.

Chillicothe, Ohio, July 26, 1886.

MISCELLANEOUS.

THE MISSOURI STATE BOARD OF HEALTH AND MEDICAL COLLEGES.—At a meeting of the Missouri State Board of Health on July 12, the following resolution was passed:

Resolved: That in future a percentage of graduates to matriculates of forty-five (45) or over, will be grounds for refusal of registration of diploma and issuing of certificate to graduates of a school otherwise in good standing; provided, however, that before such action is taken by this Board, the said school whose diploma is presented for registration, shall be notified and an opportunity be given the faculty thereof for satisfactory explanation to the State Board of Health.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 17, 1886, TO JULY 23, 1886.

Col. Glover Perin, Surgeon, leave of absence extended one month. (S. O. 165, A. G. O., July 19, 1886.)

Major Wm. H. Gardner, Surgeon, granted four months' leave, to take effect Aug. 10, or as soon thereafter as his services can be spared. (S. O. 165, A. G. O., July 19, 1886.)

Major Calvin DeWitt, Surgeon, assigned to duty at Ft. Sully, Dak. (S. O. 66, Dept. Dak., July 14, 1886.)

Capt. Richards Barnett, Asst. Surgeon, leave of absence extended six months on surgeon's certificate of disability. (S. O. 162, A. G. O., July 15, 1886.)

Capt. J. J. Kane, Asst. Surgeon, ordered from Ft. Ringgold, Tex., to Ft. Hancock, Tex. (S. O. 85, Dept. Texas, July 13, 1886.)

Capt. Wm. F. Carter, Asst. Surgeon, ordered from Ft. Concho, Texas, to Ft. Ringgold, Texas. (S. O. 85, Dept. Texas, July 13, 1886.)

Capt. Jno. M. Dickson, Asst. Surgeon, ordered from Alcatraz Island, Cal., to Ft. Mason, Cal.

Capt. Jno. J. Cochran, Asst. Surgeon, ordered from Ft. Mason, Cal., to Presidio of San Francisco.

Capt. A. J. Gibson, Asst. Surgeon, ordered from Ft. Winfield Scott, Cal., to Alcatraz Island, Cal., on return from leave of absence. (S. O. 56, Dept. Cal., July 8, 1886.)

First Lieut. Wm. O. Owen, Jr., Asst. Surgeon, ordered for duty at Ft. Schuyler, New York Harbor. (S. O. 84, Div. Atlantic, July 15, 1886.)

ORIGINAL ARTICLES.

DISEASES AND DEATHS OCCURRING IN THE MEDICAL SERVICE OF JOSEPH JONES, M.D., 1869-1886,

IN THE CHARITY HOSPITAL OF NEW ORLEANS, LA.
WITH PRACTICAL OBSERVATIONS.

(Concluded from page 119.)

CONTAGIOUS AND INFECTIOUS FEVERS AND DISEASES.

	Cases.	Deaths.
Dengue	15	
Yellow fever	76	35
Typhoid fever	16	3
Measles	10	2
Scarlatina	4	1
Diphtheria	2	
Mumps	3	
Small-pox	18	1
Asiatic cholera	2	2
Total contagious and infectious fevers and diseases	146	44

Percentage of deaths in contagious and infectious fevers and diseases, 30.1.

Ratio of deaths in 1000 cases of contagious and infectious fevers and diseases, 301.

One death from contagious and infectious fevers and diseases in 3.31 cases.

PHTHISIS PULMONALIS.

Cases, 413. Deaths, 122.

Percentage of deaths in phthisis pulmonalis, 29.5. One death in 3.38 cases. On examination, the mortality records of New Orleans will show that phthisis does not confine its ravages to more Northern cities, but is the cause of an alarming mortality even amongst the natives (creoles) of New Orleans.

About one-tenth of all the deaths occurring in New Orleans are due to phthisis pulmonalis.

Thus the total deaths in New Orleans during thirty-six years, 1844 to 1880, was 242,426, and of this number phthisis caused 24,071. During the period just specified (1844-1880, thirty-six years) the principal diseases occasioned the following number of deaths, as shown by the following table:

DEATHS IN NEW ORLEANS FROM SOME OF THE PRINCIPAL DISEASES DURING A PERIOD OF 36 YEARS—1844-1880.

Diseases.	Deaths.
Cholera (Asiatic)	11,847
Cholera morbus	889
Cholera infantum	2,408

15,144

Enteritis	6,915	
Diarrhoea	8,289	
Dysentery	7,097	
Phthisis pulmonalis		22,301
Small-pox, scarlet fever and measles	9,381	24,071
Dengue, typhus, typhoid fever, cerebro-spinal fever and simple continued fever	5,932	
Yellow fever	28,739	
Various forms of malarial fever	12,416	
Total fevers		56,468

Grand total deaths caused by the preceding diseases... 117,984

Whilst fevers of all varieties destroyed, in the city of New Orleans, 56,478 citizens in thirty-six years, yellow fever destroyed only about one-half this number, namely, 28,739 citizens in thirty-six years; and notwithstanding that, only about one-half of the mortality from fever in New Orleans during the period specified was due to yellow fever. The attention of the citizens of the entire Mississippi Valley is directed to this disease. Congestive fever alone destroyed in New Orleans, during thirty-six years, 6,337 persons; phthisis pulmonalis destroyed nearly as many citizens as yellow fever, namely, 24,071; enteritis, dysentery and diarrhoea, 22,301; and cholera, cholera morbus and cholera infantum, 15,144. Total deaths from phthisis pulmonalis and bowel affections, 61,516.

Those diseases which are common to the entire Valley caused 61,516 deaths, excluding those caused by fevers, 56,478. Fevers, bowel affections and phthisis pulmonalis caused in New Orleans 117,994 deaths in thirty-six years, out of a total deaths from all causes 242,426.

The statistics afforded by the Charity Hospital of New Orleans are no less instructive. During a period of eighteen years preceding the American civil war—1842-1860—there were treated in the wards of the Charity Hospital of New Orleans 5690 cases of phthisis pulmonalis, of which 3084 terminated fatally; giving 54.1 per cent. mortality. During the seventeen years following the civil war there were treated in the Charity Hospital 5251 cases of phthisis pulmonalis, of which 2525, or 40.8 per cent., died. During a period of thirty-eight years—1842-1880—10,950 cases of phthisis pulmonalis were treated in the wards of the Charity Hospital, 5669, or 51.2 per cent. of which terminated fatally.

Whilst the statistics of the Charity Hospital refer chiefly to the laboring classes, and to those who have been reduced in their circumstances by misfortunes and disease, at the same time we have shown that

the statistics of the city at large illustrate to an equal extent the destructive effects of the insidious disease.

During a period of years extending from 1845 to 1881, the deaths from phthisis pulmonalis have, with the exception of a single year, annually exceeded half a thousand, and in many years have been more than eight hundred. During ten years—1845-1858—(the records of those years which were imperfect being, as in all other estimates, excluded), the deaths from phthisis pulmonalis in New Orleans numbered 6367; during ten years—1859-1869—7251; during eleven years—1870-1881—9016; we have thus, during a period of thirty-one years—1845-1881—a grand total of 22,958 deaths by phthisis pulmonalis.

Surely a disease which steadily claims its victims each year, which in any long series of years has been as destructive as the dreaded yellow fever, should secure the earnest consideration of those charged with the sanitary affairs of this and other cities.

The epidemic of 1878 threw the professional minds of a certain order into a state of morbid excitability on the subject of yellow fever, and the public has been scared with numerous lucubrations on the subject, and quarantine, and the National and State Legislatures have been repeatedly and freely plied with advice and urged to provide money and places for the self-constituted guardians of public health and foreign and inter-State commerce. In comparison with phthisis pulmonalis, which every year destroys its thousands and tens of thousands in every State in this Union, yellow fever should be regarded only as a casual and minor disease, visiting only certain limited portions of the tropical and temperate regions, at long intervals. We hear much of the cost of epidemics, but nothing as to the fearful cost of such a disease as phthisis, which holds its doomed victims in deadly embrace for months and even years, and inflicts, in addition to indescribable tortures, vast, serious pecuniary expenses.

I have given stern facts, with the design of arousing the attention of the medical profession to some of the prominent causes of this disease, and have ventured to suggest some modes of prevention. The necessity of personal and domestic sanitation should appeal to all alike. The people may escape the yellow fever by leaving the infected places, but they cannot escape those causes of disease which spring from the habits, mode of living, and climate, and which are ever present with them, in their assemblies, counting-houses and dwellings, around their firesides and in their beds, devoted to quiet and rest. The chief causes of the prevalence of phthisis pulmonalis in New Orleans appear to be:

1. Imperfect drainage.
2. The saturation of the atmosphere with moisture.
3. Imperfect construction of houses.
4. Imperfect ventilation of houses.
5. Crowding.
6. The neglect of regular exercise for diversion and recreation.
7. Imperfect nourishment.
8. Hereditary taint.
9. Imperfect warming and drying of the houses by fire during the winter months.

10. The wearing of insufficient clothing during the winter months.

A volume might be written on the preceding causes, but our object is clearly to present practical observations which may prove of benefit to those interested.

Owing to the peculiar topography and geographical situation of New Orleans, the soil is saturated with moisture, and the atmosphere is habitually near the dew point. The *old* city (second district, bound by Esplanade and Rampart streets), and large portions of the third, fourth and first districts, are compactly built with brick, and the sudden changes of the fall, winter and spring are frequently manifested by the precipitation of moisture on the cold walls in the form of streams of water. Dampness checks the cutaneous perspiration; it abstracts the normal heat and electricity from the body; it receives and holds the noxious exhalations from the human body, and from all other sources, and it promotes the development and rapid multiplication of low or simple forms of vegetable and animal life, and more especially of micrococci bacilli, bacteria, and fungi.

In many instances no attention has been paid to the proper filling in, with sand and gravel, of building lots, and stagnant water frequently stands under the houses, and is a potent source of disease. Whole blocks can be pointed out in the heart of this great city in which there is no proper ventilation, and in which the lowest floor rests directly upon the damp earth. Houses, churches, school-houses, stores, and all buildings inhabited or occupied by human beings, should be thoroughly ventilated laterally and perpendicularly. As far as practicable the respired air should be diluted and as far as possible robbed of its noxious properties. The air should circulate freely under the lower floor of every house, and should be admitted by ventilation in the front and rear of each room, and if possible on all sides; and a system of ventilation should be so arranged as to allow of the escape of the foul air of the sleeping apartment directly up through the roof. Each room should have a direct supply of fresh air from the outside. *If people would send for the carpenter and properly ventilate their houses, they would not so often need his services in the grave-yard.*

The effect of imperfect ventilation and close confinement and crowding, with insufficient food, is fully illustrated by the frequent occurrence of phthisis pulmonalis among females who are compelled to live by the needle and sewing machine, and who occupy small unventilated houses resting upon the ground.

Warm clothing, regular exercise in the open air, nutritious food, and such thorough ventilation as shall at all times secure pure air in the store, work-shop, sitting room and bed room, are the great means of preventing the development of phthisis pulmonalis. War destroys its thousands, but phthisis claims its tens of thousands.

The improvidence, ignorance and avarice of mankind, as manifested in the neglect of sanitary laws, in the construction and conduct of dwelling houses, stores, factories, school houses, and churches, are more destructive to human life than yellow fever and all other pestilences.

TREATMENT OF PHTHISIS.

In hospital practice amongst charity patients, the results of treatment will depend upon the stage of the disease; the extent to which the lungs and other organs have been involved by the tubercular deposits; the constitution of the patient; the habits and condition of the patient before the onset of the disease; the cause of the disease, the absence or existence of *heredity*. The experience of the author is to the effect that good results may be achieved in almost all cases, and that the progress of the disease may frequently be temporarily arrested.

The remedies of greatest value appear to be cod-liver oil, phosphates, hypophosphates of zinc, iron, sodium, potassium, strychnia, and the bitter tonics.

Throughout the entire term of hospital service cod-liver oil maintained its place at the head of the list of the remedies adapted to the treatment of phthisis. The following combination was found useful as a tonic: *R.* Tincture of nux vomica, f ʒiv; syrup of hypophosphates of iron, lime, soda, potassium, f ʒviij; mix; dose, one teaspoonful three times a day.

To allay cough the following formulas were frequently used: *R.* Syrup of morphia (one grain of sulphate of morphia to one fluid ounce of simple syrup), f ʒij; syrup of squills, f ʒi; syrup of ipecac, f ʒiv; syrup of tolu, f ʒiiss; dose, from one to two fluid drachms when necessary. *R.* Syrup of morphia, f ʒij; syrup of squills, f ʒi; syrup of prunus Virginiana, f ʒiv; mix; dose, from one to three fluid drachms when necessary.

Alcoholic stimulants administered in a diluted state, with cane sugar, proved beneficial in arresting the waste of tissue.

When good whiskey is diluted with four parts of sweetened water in many cases it acts as a nutrient and anæsthetic, allaying the cough and inducing sleep.

SOUTHERN RETREATS, OR HOSPITALS, FOR THE ACCOMMODATION AND TREATMENT OF CASES OF PHTHISIS PULMONALIS.

The Southern region of Louisiana, on the East bank of the Mississippi, beyond the borders of Lake Pontchartrain, the adjoining *Pine Belt* above the coast of Mississippi, presents a very mild climate, well adapted to the accommodation of persons from all sections of the United States, but more especially from the Northern or Western States, who are suffering with phthisis. The atmosphere of the Gulf, immediately along the borders, is too stimulating to the bronchial mucous membranes in many cases of phthisis pulmonalis; and the Delta of the Mississippi Valley affords too much moisture, and is the seat of too much fog and rain, to afford satisfactory results in the treatment of phthisis.

The belt of country around Covington, and the Abita Springs, across the Lake from New Orleans, is composed chiefly of sand, and is covered with the long-leaf pine. Owing to the porous nature of the soil, no water lies after rains; the atmosphere is comparatively dry, and the balsamic properties of the pine are exhaled.

There are statistics to show that the death rate from phthisis in this Pine Belt of the Florida parishes of Louisiana is lower than that of any other portion of the United States. I have sent many patients suffering with phthisis to this region, and have for many years advocated the founding of retreats or hospitals for the treatment of this disease in this portion of Louisiana.

My colleague, Prof. Payne, of Galveston, Texas, has suggested that convalescents from the Charity Hospital, and especially those suffering with phthisis, might with benefit to the patients and to the institution, be transferred to a hospital located in a healthy region, outside of the limits of the Parish of Orleans. Assistance might be rendered in the support of such an institution by the labor of the patients in cultivating flowers, vegetables and fruits.

GENERAL DISEASES, CONTINUED.

	Cases.	Deaths.
Elephantiasis Græcorum (Oriental leprosy).....	5	3
Elephantiasis Arabum.....	3	
Zaros (African).....	1	
Scrofula.....	14	3
Scurvy.....	7	
Purpura hæmorrhagia.....	8	
Total.....	38	6
Medullary cancer.....	2	
Epithelial cancer.....	1	
Osteoid cancer.....	2	2
Schirrus cancer.....	2	
Cancer of the uterus.....	1	
Cancer of the stomach.....	1	1
Cancer of the pylorus and pancreas.....	1	1
Cancer of the liver.....	2	2
Cancer of the testicle and mesenteric glands.....	1	1
Cancer of the rectum.....	1	
Cancer of the tongue.....	1	1
Cancer of the penis.....	1	
Total.....	16	8
Erysipelas.....	19	2
Acute articular rheumatism.....	152	2
Chronic articular rheumatism.....	157	2
Muscular rheumatism.....	17	
Gonorrhœal rheumatism.....	6	
Syphilitic rheumatism.....	30	
Gout (chronic).....	1	
Primary syphilis.....	34	
Secondary syphilis.....	120	2
Total.....	536	8

Grand total general diseases, including all the forms of malarial and other fevers, phthisis and other constitutional diseases: Cases, 4,034; deaths, 276. Per cent. of deaths, in general diseases, 6.83; rates of deaths in 1,000 cases general diseases, 68.3. One death from general diseases in 14.6 cases.

It is evident from the preceding figures that whilst the malarial (paroxysmal fevers) numbered 2,885 cases out of a total of 4,037 cases of constitutional diseases, or about 71.2 per cent.; on the other hand, the mortality occasioned by malarial fevers was only 88 out of 276 deaths from all general diseases. The mortality occasioned by the various forms of malarial fever was only about 31 per cent. of the mortality occasioned by all general diseases, including the former.

We will now examine the numerical relations of

the local diseases treated by the author in the Charity Hospital of New Orleans, during the periods already specified.

LOCAL DISEASES.

Diseases of the Nervous System.

	Cases.	Deaths.
Meningitis.....	8	2
Cerebritis.....	2	2
Softening of the brain.....	7	3
Abscess of the brain.....	2	2
Syphilitic tumor of base of brain.....	1	1
Apoplexy (cerebral hæmorrhage).....	15	11
Cerebro-spinal sclerosis.....	1	1
Spinal meningitis.....	9	2
Myelitis.....	1	1
Atrophy of spinal cord.....	2	1
Sclerosis of spinal cord.....	6	
Hæmiplegia.....	59	12
Paraplegia.....	34	4
Paralysis caused by fear.....	8	1
Paralysis agitans.....	5	
Epilepsy.....	40	2
Locomotor ataxia.....	6	
Sciatica.....	8	
Facial neuralgia.....	27	
Chorea.....	1	
Dementia.....	13	
Dementia and general paralysis.....	6	2
Insanity.....	7	1
Tetanus.....	1	
Sunstroke (thermic disease.).....	3	1
Alcoholism (delirium tremens).....	170	9
Total diseases of the nervous system.....	442	58

Many of the cases of epilepsy were traced to the habit of self-abuse, and four of the cases of dementia and general paralysis were traced to the same cause. Without doubt a considerably larger number of these and other nervous disorders were induced originally by self-abuse and excessive indulgence of the sexual appetite; but the absolute reticence of many patients with regard to their personal history in such matters precludes the demonstration of the cause beyond all doubt. Six cases of epilepsy were referable to blows inflicted upon the crania during health, causing fractures and depressions of the bones.

Many of the cases of cerebro-spinal disease, dementia, general paralysis, paraplegia and hæmiplegia, appeared to have their origin in the abuse of alcoholic stimulants.

Diseases of the Circulatory System.

Heart; valve disease; mitral.....	30	11
Heart; valve disease; tricuspid.....	1	
Aortic pulmonary and tricuspid valves.....	8	3
Fibrous concretion in heart.....	1	1
Hypertrophy and dilatation of heart.....	1	
Hypertrophy, dilatation and valvular disease.....	20	10
Fatty degeneration.....	4	3
Palpitation and irregular action.....	2	
Pericarditis.....	1	
Aneurism of ascending aorta.....	10	2
Fatty and calcareous degeneration of heart and arteries.....	1	1
Aneurism of arch of aorta.....	5	3
Aneurism of carotid.....	1	
Aneurism of descending aorta.....	1	
Aneurism of abdominal aorta.....	4	1
Valvular disease of heart and aneurism.....	1	1
Total diseases of heart and blood-vessels.....	91	36

Per cent. of deaths in diseases of heart and blood-vessels, 3.9.

Diseases of the Absorbent System.

	Cases.	Deaths.
Non-Syphilitic bubo.....	1	
Scrofulous disease of glands.....	1	
Disease of renal capsules (Addison's disease).....	1	1
Total diseases of absorbent system.....	3	1

Diseases of the Respiratory System.

Bronchitis.....	160	4
Vesicular emphysema.....	1	
Asthma.....	49	3
Gangrene of lungs.....	1	1
Pneumonia.....	152	32
Pneumonia (double).....	41	21
Pleuro-pneumonia.....	16	6
Pleuro-pneumonia (double) supervening on malarial fever.....	4	4
Pleuro-pneumonia supervening on phthisis.....	2	2
Abscess of lungs.....	2	1
Laryngitis, acute.....	7	2
Pleuritis.....	47	3
Hydrothorax.....	6	1
Pneumo-thorax.....	3	1

Total diseases of respiratory organs.....491
Per cent. of diseases of respiratory organs, 16.7.

Diseases of the Alimentary Canal.

Inflammation of fauces and palate.....	1	
Ptyalism.....	1	
Tonsillitis.....	6	
Pharyngitis.....	3	
Trachitis.....	4	
Dyspepsia.....	4	
Gastritis.....	10	
Gastralgia.....	1	
Gastro-enteritis and jaundice.....	2	
Gastro-enteritis.....	5	
Cholera morbus.....	10	
Enteritis.....	7	
Dysentery, acute.....	122	17
Dysentery, chronic.....	90	42
Diarrhoea, acute.....	160	7
Diarrhoea, chronic.....	125	25
Dysentery and diarrhoea, chronic.....	131	30
Constipation.....	5	
Hernia.....	6	
Obstruction of bowels.....	2	
Hæmorrhoids.....	8	
Fistula in ano.....	2	
Prolapsus of anus.....	1	
Abscess of rectum.....	1	
Cancer of rectum.....	1	
Peritonitis.....	1	

Total diseases of alimentary canal...709
Per cent. of deaths, diseases of alimentary canal, 17.3.

It will be observed that in the class of diseases of the alimentary canal, acute diarrhoea and acute dysentery occasioned 282 cases, with 24 deaths; and chronic diarrhoea and dysentery 346 cases and 9 deaths; the mortality being relatively greater in the chronic than in the acute forms of these diseases.

Many of the cases were brought in wretched condition from the swamps along the railroads and from the rice-fields above and below New Orleans on the banks of the Mississippi and its tributaries, or were complicated by the action of the malarial poison.

Diseases of the Liver.

Hepatitis.....	24	6
Hepatitis and abscess of liver.....	12	7

	Cases.	Deaths.
Cirrhosis of liver, with ascites and anasarca of liver.....	31	21
Adenoma and cirrhosis of liver.....	1	1
Jaundice.....	10	
Fatty degeneration of liver.....	3	
Amyloid degeneration of liver.....	1	
Hydatids of liver.....	1	1
Tuberculosis of liver.....	1	1
Obstruction of common bile duct and jaundice.....	1	1
Total.....	85	38
Per cent. of deaths in diseases of the liver, 44.7.		

Diseases of the Spleen.

Splenitis.....	2	
Hypertrophy of spleen.....	1	
Leucocythæmia.....	1	1
Total.....	4	1

The following facts should be noted with reference to the preceding classification of the diseases of the liver and spleen: The cases recorded as jaundice did not represent the number of cases presenting this symptom; for almost every case of yellow fever, and a large number of the various forms of malarial fever, as well as some cases of hepatitis, cirrhosis and pneumonia were jaundiced. Every case of prolonged malarial fever presented more or less hepatic derangement and enlargement of the spleen, but the secondary derangements were included under the head of the original malarious diseases.

Diseases of the Kidneys.

Bright's disease of the kidneys.....	80	24
Acute nephritis.....	2	1
Diabetes mellitus.....	3	1
Diabetes insipidus.....	2	
Renal calculi.....	1	
Total.....	88	26

Per cent. of deaths in diseases of the kidneys, 39.4.

Diseases of Bladder and Male Organs of Generation.

Cystitis.....	6	
Enlarged prostate.....	1	
Stricture.....	9	
Urinary fistula.....	1	
Vesico-vaginal fistula.....	1	
Gonorrhœa.....	25	
Hæmorrhage from urethra.....	1	
Varicocele.....	4	
Cancer of the penis.....	1	
Phymosis.....	3	
Hydrocele.....	6	
Orchitis.....	10	
Syphilitic enlargement and induration of the testicle.....	2	
Total diseases of the bladder and male organs of generation.....	70	—

Diseases of Female Organs of Generation.

Gonorrhœa.....	5	
Prolapsus uteri.....	2	
Amenorrhœa.....	1	
Myalitis.....	3	
Abortion.....	3	
Vesico-vaginal fistula.....	1	
Recto-vaginal fistula.....	2	
Fibrous tumor of uterus.....	2	1
Cancer of uterus.....	1	
Total diseases of female organs of generation.....	20	1

fessor Frank Hawthorne, and here the cases of female diseases appear amongst my records.

Diseases of the Organs of Locomotion.

	Cases.	Deaths.
Caries and necrosis of bones.....	6	
Synovitis.....	4	
Caries of spine, with curvature.....	2	
Psoas and lumbar abscesses.....	3	1
Total.....	15	1

Diseases of the Cutaneous System.

Urticaria.....	2	
Psoriasis.....	5	
Pemphigus.....	1	
Scabies.....	5	
Eczema.....	2	
Total.....	15	—

Diseases of the Eye, Nose and Ear.

Conjunctivitis.....	1	
Puulent ophthalmia.....	1	
Gonorrhœal ophthalmia.....	2	
Scrofulous ophthalmia.....	1	
Opacity of cornea.....	3	
Syphilitic iritis.....	3	
Scrofulous iritis.....	2	
Cataract.....	4	
Blindness.....	6	
Ozæna.....	1	
Otorrhœa.....	1	
Total.....	25	—

Injuries, Ulcers and Abscesses.

Burns and Scalds.....	6	
Ulcers.....	28	1
Amputations of lower extremities for ulcers.....	3	1
Gangrene of both feet—resulting from exposure to cold during nights in Louisiana Swamp—amputation of both feet.....	1	
Concussion of brain.....	6	3
Contusion of head.....	1	
Contusion of back.....	5	
Contusion of abdomen.....	4	
Fractures.....	5	
Fracture of femur in old age.....	1	1
Incised wounds.....	6	
Dislocations.....	2

The mode in which I have grouped the different diseases is not free from certain objections. Thus I have classed *alcoholism* (delirium tremens) and *mania a potu* under the head of nervous diseases, whilst the effect of alcohol might with almost equal propriety be classed under the head of poisons. As the habitual use and abuse of alcoholic stimulants leads to fatty degeneration, hepatic derangements, cirrhosis of the liver and kidneys, exhausted nerves and intellectual forces, and other abnormal conditions, it is evident that *alcoholism*, delirium tremens, and *mania a potu* might also with equal propriety be classed with *general diseases*. Nevertheless, as the most prominent symptoms caused by the excessive use of alcohol in patients transferred from the streets and crowded habitations of the poor to the crowded wards of a hospital, are referable to the nervous system, such as wild delirium, sleeplessness, muscular and nervous agitation, it is evident that for all practical purposes those suffering from the effects of alcohol may be classed as in the preceding tabulated statements.

The preceding facts are significant, showing that alcohol does not destroy its victims, in most cases, suddenly, as in the dead sleep of profound intoxication, or in the wild maniacal ravings of delirium tremens. By slow and measured steps, in most cases by inducing cirrhosis of the liver, Bright's disease of the kidneys, anasarca, ascites, rheumatism, rheumatic gout, defected vision, fatty degeneration of the heart, arteries and muscular system, which finally end in paralysis, imbecility and insanity, alcohol encircles its victims in irremediable and everlasting ruin.

Without doubt, *alcohol* occasions a vast amount of disease over the face of this mighty Republic, and carries death, destruction, dishonor and shame into thousands of happy homes. Alcohol is at the bottom of a large proportion of the crimes committed in the United States. Alcohol dethrones reason and poisons the fountains of sentiment and morals, and is even more destructive upon the moral and intellectual nature than upon the physical organism of man.

Per cent. of deaths from all causes, 10.4. Ratio of deaths per 1,000, 104. One death in 9.44 cases.

If a comparison be instituted between the rate of mortality in the cases under the immediate care of the author, and the general statistics of the Charity Hospital, we obtain the following data, which we have consolidated at the expense of much time and labor:

During eighteen years preceding the civil war (1842-1861) the total admissions into the Charity Hospital of New Orleans were 207,356; total deaths, 29,614; per cent. of deaths, 14.2.

During the sixteen years following the civil war, (1864-1881), total admissions, 96,857; total deaths, 14,104; per cent., 14.5.

Total admissions during thirty-four years, 304,213; total deaths, 43,718; per cent. of deaths in the Charity Hospital of New Orleans during the thirty-four years specified, 14.3.

The greater proportion of the cases of fever and of all other diseases treated by the author in the Charity Hospital during the period specified (1869-1886), were natives of foreign countries and of surrounding States. Many had resided in Louisiana only a short time, not exceeding one year in the United States; whilst many were brought directly to the wards of the hospital from the swamps and rice-fields of the Delta of the Mississippi River within a few months after their arrival from Europe.

Upon a careful examination and classification of statistics of the Charity Hospital of New Orleans during the period of forty years (1836-1876) we find that 310,659 patients were admitted; and of this number 248,011 were foreigners, 55,403 natives of the United States outside of Louisiana, and only 11,671 were natives of Louisiana.

During the entire period of the hospital service of the author, similar relations with reference to nativity existed amongst the patients under his charge and treatment.

Thus, during a term of service extending from October 1, 1884, to April 1, 1885, of a grand total of 547 cases treated by the author in the Charity Hospital, only forty-two were natives of Louisiana, and of them only eighteen were natives of New Orleans, the remaining twenty-four having been born in the various parishes of Louisiana. Of the sixty-three deaths occurring during the period, only two were natives of New Orleans, and the cause of death was the same in both, viz., *phthisis pulmonalis*. Amongst the twenty-four natives of the other parishes of Louisiana four deaths occurred, by the following diseases: Chronic Bright's disease, chronic dysentery, pernicious malarial fever, malarial toxæmia or cachexia of long standing, with enlarged spleen, anæmia and general anasarca.

The natives of Louisiana constituted only 7.6 per cent. of all the cases treated, and the mortality 9.2 per cent. of the deaths from all causes.

During a term of hospital service extending from October 1, 1885, to April 1, 1886, of a grand total of 323 cases of all diseases treated by the author, eleven were natives of New Orleans and sixty of the parishes outside of the limits of the parish of

Orleans. The foreigners and natives of other States of the Union numbered 252.

RELATIVE MORTALITY IN THE WHITE AND NEGRO RACES IN NEW ORLEANS.

The statistics which the author has presented, illustrating the general results of his medical practice in the Charity Hospital, relate almost exclusively to the *white race*; the occasional presence of Chinese, Japanese, Malays, Arabs, and whites tinged with negro blood in his wards, could not afford sufficient material for calculation as far as the diseases and mortality of different races were concerned. Preceding the civil war the number of colored people treated in the Charity Hospital was comparatively small. But since the emancipation of the negro slaves the number of negroes applying annually to be treated in this institution has increased.

It is well known that the colored race form a larger proportion of the population of New Orleans than of any other American city, and at the same time it has been established that the death-rate of the colored population exceeds that of the whites in American cities.

I have prepared the following table, illustrating the mortality of New Orleans for a series of years, giving the death-rate for whites and colored:

MORTALITY OF NEW ORLEANS, LOUISIANA.

Death-rate per 1,000 Inhabitants.

Year.	White.	Colored.	Total.
1845.....	25.10.....	22.50.....	24.32
1847.....	70.86.....	37.08.....	62.03
1849.....	81.02.....	62.91.....	77.44
1850.....	63.08.....	52.10.....	59.38
1852.....	67.91.....	43.04.....	62.90
1853.....	124.68.....	48.98.....	110.00
1856.....	32.98.....	35.66.....	33.89
1857.....	34.86.....	38.07.....	35.49
1858.....	69.64.....	80.37.....	72.70
1859.....	33.58.....	86.78.....	41.53
1860.....	41.99.....	52.79.....	43.51
1861.....	31.58.....	37.16.....	31.87
1863.....	37.30.....	59.53.....	41.35
1864.....	42.14.....	81.75.....	49.86
1865.....	33.32.....	60.88.....	38.99
1866.....	36.77.....	65.56.....	42.52
1867.....	56.79.....	47.80.....	54.69
1868.....	25.49.....	38.97.....	28.60
1869.....	27.24.....	44.80.....	31.75
1870.....	31.74.....	52.20.....	38.61
1871.....	27.26.....	42.76.....	31.32
1872.....	27.29.....	41.93.....	31.17
1873.....	32.79.....	51.42.....	37.73
1874.....	29.53.....	43.44.....	33.75
1875.....	26.28.....	40.25.....	30.00
1876.....	25.87.....	42.50.....	30.31
1877.....	25.96.....	49.02.....	32.11
1878.....	52.05.....	39.94.....	48.81
1879.....	20.85.....	34.41.....	23.95
1880.....	22.96.....	34.38.....	26.01
1881.....	25.79.....	38.95.....	29.31
1882.....	21.89.....	39.03.....	26.45

During the period of thirty-two years embraced in the above table, with the exception of the year 1870, the death-rate amongst the whites was the lowest in 1882.

The average death-rate for the thirty-two years amongst the whites was about 39.6; and for the colored people about 47.1. I observe a marked diminution of the death-rate amongst the whites during the last four years of this table, which ranged from 20.85 to 25.79 per 1,000 white inhabitants per annum.

These figures (1879-1882) will compare favorably with those of cities in which the vast proportion of

the inhabitants belong to the white race. Thus, during the same years (namely, 1879, 1880, 1881 and 1882), the death-rate in Boston ranged between 20.38 and 33.53; New York 25.82 to 31.08; Brooklyn, 21.09 to 24.84; Philadelphia, 17.17 to 22.62; Pittsburgh, 19.49 to 27.23; St Louis, 18.01 to 22.07; Chicago, 18.01 to 25.69.

When it is considered that New Orleans receives a vast number of sick whites from all the States tributary to the Mississippi River, in her great and noble Charity Hospital, as I have shown by the statistics recorded in this paper, and also by the elaborate and extended statistics which the author has published as President of the Board of Health of the State of Louisiana 1880, 1881, 1882 and 1883; and when it is still further noted, that the deaths of these strangers and aliens are recorded to the credit of New Orleans, it is evident that the mortality rate amongst her white inhabitants will compare favorably with that of any American city. Of course we exclude from this statement the ravages of foreign pestilence, and more especially Asiatic cholera and yellow fever.

The results of the rigid system of quarantine and of domestic and maritime disinfection and sanitation established and conducted during the four years in which the author held the position of President of the Board of Health of the State of Louisiana (1880, 1881, 1882, 1883), lead us to hope that foreign pestilence may be forever excluded from the Valley of the Mississippi.

156 Washington St., Fourth District, New Orleans, La., May 1, 1886.

MECHANICAL TREATMENT OF RETROVERSION OF THE UTERUS.¹

BY HENRY T. BYFORD,

PHYSICIAN AND SURGEON TO THE WOMAN'S HOSPITAL OF CHICAGO.

Retroversion of a fully developed uterus, in which there is no flexion, presupposes a displacement of the os and lower end of the cervix forward. Causes of retroversion act by either weakening the natural supports or bringing an abnormal or unusual strain to bear upon them. The mechanical treatment, or that which corrects the displacement while a cure is being accomplished, or attempted, should avoid weakening or interfering with the natural supports.

We may divide the more directly mechanical means usually adopted for correction of such deformity into four kinds.

1. Those which permanently fix the fundus in front of the pelvic axis.
2. Those which draw or fix the os or cervix back of the pelvic axis.
3. Those which place a barrier or obstacle to the forward displacement of the os and cervix.
4. A combination of two or more of these methods.

The fixation of the fundus forward has been done in four principal ways:

1. By the Alexander operation, in shortening the round ligaments. It was suggested by Alquié, recom-

¹ Read before the Chicago Medical Society, July 6, 1886.

mended by Aran, experimented upon on the cadaver by W. A. Freund, and successfully performed and established as a therapeutic measure by W. Alexander.

2. The stitching of one (or both) round ligaments to the abdominal walls, as has been done by William H. Byford while performing laparotomy for another purpose. An examination after two menstrual periods had passed showed that the uterus was still held up by its new attachment.

3. Stitching a broad ligament to the abdominal wall, as has been successfully done by Kœberlé and Schroeder during laparotomy for another pathological condition. The uterus in Kœberlé's case was found upon examination by Carl Braun, after ten years, to have retained its new position.

4. The stitching of the uterus to the abdominal wall, as recommended by Mueller and Lawson Tait, and performed by Skene Keith, Haywood Smith and probably others by an especial laparotomy.¹

These operations have the common disadvantage of an unnatural fixation of the fundus forwards. Drawing or holding of the cervix back has been accomplished by the hazardous expedient of cauterizing the vagina for the purpose of producing cicatricial contraction behind the cervix, as by Amussat and others, or of causing adhesive inflammation in the posterior cervical and vaginal walls; or by the safer plan of denuding these apposed surfaces and stitching them together, as recommended by W. Lœwenthal and performed by Hunter, of New York, O. E. Herrick, of Michigan, and others.

The objection to such procedure, besides the danger of peritonitis, lies in the fact that either the cervix must be held back rigidly, or the posterior vaginal attachments must become loosened. Emmett thinks that the consequent traction upon the bladder must be a serious objection.

But the most common and available method is by pessaries of the Hodge class, such as the Albert Smith, Thomas, Emmett, Hewitt, Hanks, Nøgerath, Schroeder, Gehrung, etc., which press backwards and upwards behind the cervix, and thus draw it back and drop the fundus forwards. They hang up the cervix, and thus supplement or supplant the posterior suspensory or sacro-uterine ligaments of the uterus. But in doing this they are apt to hold the uterus in a state of forced ante flexion, and weaken or irritate these ligaments; and by stretching the vagina longitudinally to loosen its attachments.

The pessaries with external supports such as Priestly's, Lazarewitsch's, Cutter's, Thomas', Scott's, can often be introduced by the patient, and thus sometimes serve a better purpose than those just mentioned. I have never used a pessary with more satisfaction than occasionally Scott's in case of relaxed vaginal outlet.

H. Marion Sims has recently² presented a retroversion stem pessary in which the cervix is pulled back by the intra-uterine stem instead of a post-cervical bar. The bar of a Hodge pessary practically passes under the cervix and affords a hinge-like support to

the stem. There are undoubtedly atrophic or imperfectly developed uteri with retroversion for which this instrument will be found preferable to others.

In some cases of small vagina and cervix, the elastic ring of Peaslee, Mayer, or Dumont-Pallier, or an inflated rubber bag or ring, or a hard rubber round or oval ring, may be made to distend the vagina and thus draw the cervix into a less abnormal position. But the majority of them are relics that belong more to history than to practice, which we take out oftener than we introduce, yet which occasionally do some good where others cannot be used. They remind us that no form of pessary can be used for all cases, and reproach us for having no suitable pessary for many cases.

The method of keeping the cervix and os back by placing an obstacle in front of it, acts upon a rational principle, and does not labor under the disadvantage of supplanting, and thus favoring atrophy of natural supports, irritating or pressing upon tender and inflamed tissues behind the cervix, of greatly stretching the vagina, of drawing open lateral lacerations of the cervix, or of holding the uterus in a state of harmful immobility. This may be accomplished by a pessary or by a plastic operation.

Pessaries of this class should keep the cervix so far back that the abdominal pressure will force the fundus forward or, in case the ligaments are utterly relaxed and useless, should hold the cervix so near the hollow of the sacrum that the fundus will, for want of space, be unable to fall back into a permanent state of retroversion. The simplest and least objectionable form is the cotton plug, which is made into a shape resembling a small pool of thread, saturated with glycerine or some other disinfected lubricant, placed transversely in front of the retroverted cervix, and changed every day. After a time the patient may take the plug out at night and have it introduced in the morning. Some patients learn to use them themselves.

A rectal tampon which was recommended by Huguier in 1865, might be made to act efficiently in this way in exceptional cases in which nothing can be retained or tolerated in the vagina, especially if the weakened perineal body were supported at the same time by a perineal pad. A flattened globe of glass, hard rubber or hollow metal of appropriate size, might for want of something better be occasionally used by the patient with comparative comfort and benefit.

Courty's pessary consists of two bars which rest on the pelvic floor, and are joined by a cross bar in front where they rest against the pubes or vaginal entrance. Behind, the bars curve up in front of the cervix, and form a more or less rigid barrier to its forward movement.

Gehrung's instrument has the shape of a very small excessively curved Albert Smith pessary, with the cross bar in front of the cervix. The chief objections to it are that the pressure against the cervix must be constant, and hence, unbearable, to keep either it or the uterus in place, and that the vaginal walls are apt to be held apart.

¹ The methods of these operators, I have not for want of time and opportunity been able to determine.

² New York Obstetrical Society, April 6, 1886.

¹ The *anteversion* pessary, called "Gehrung's pessary," is not the one referred to.

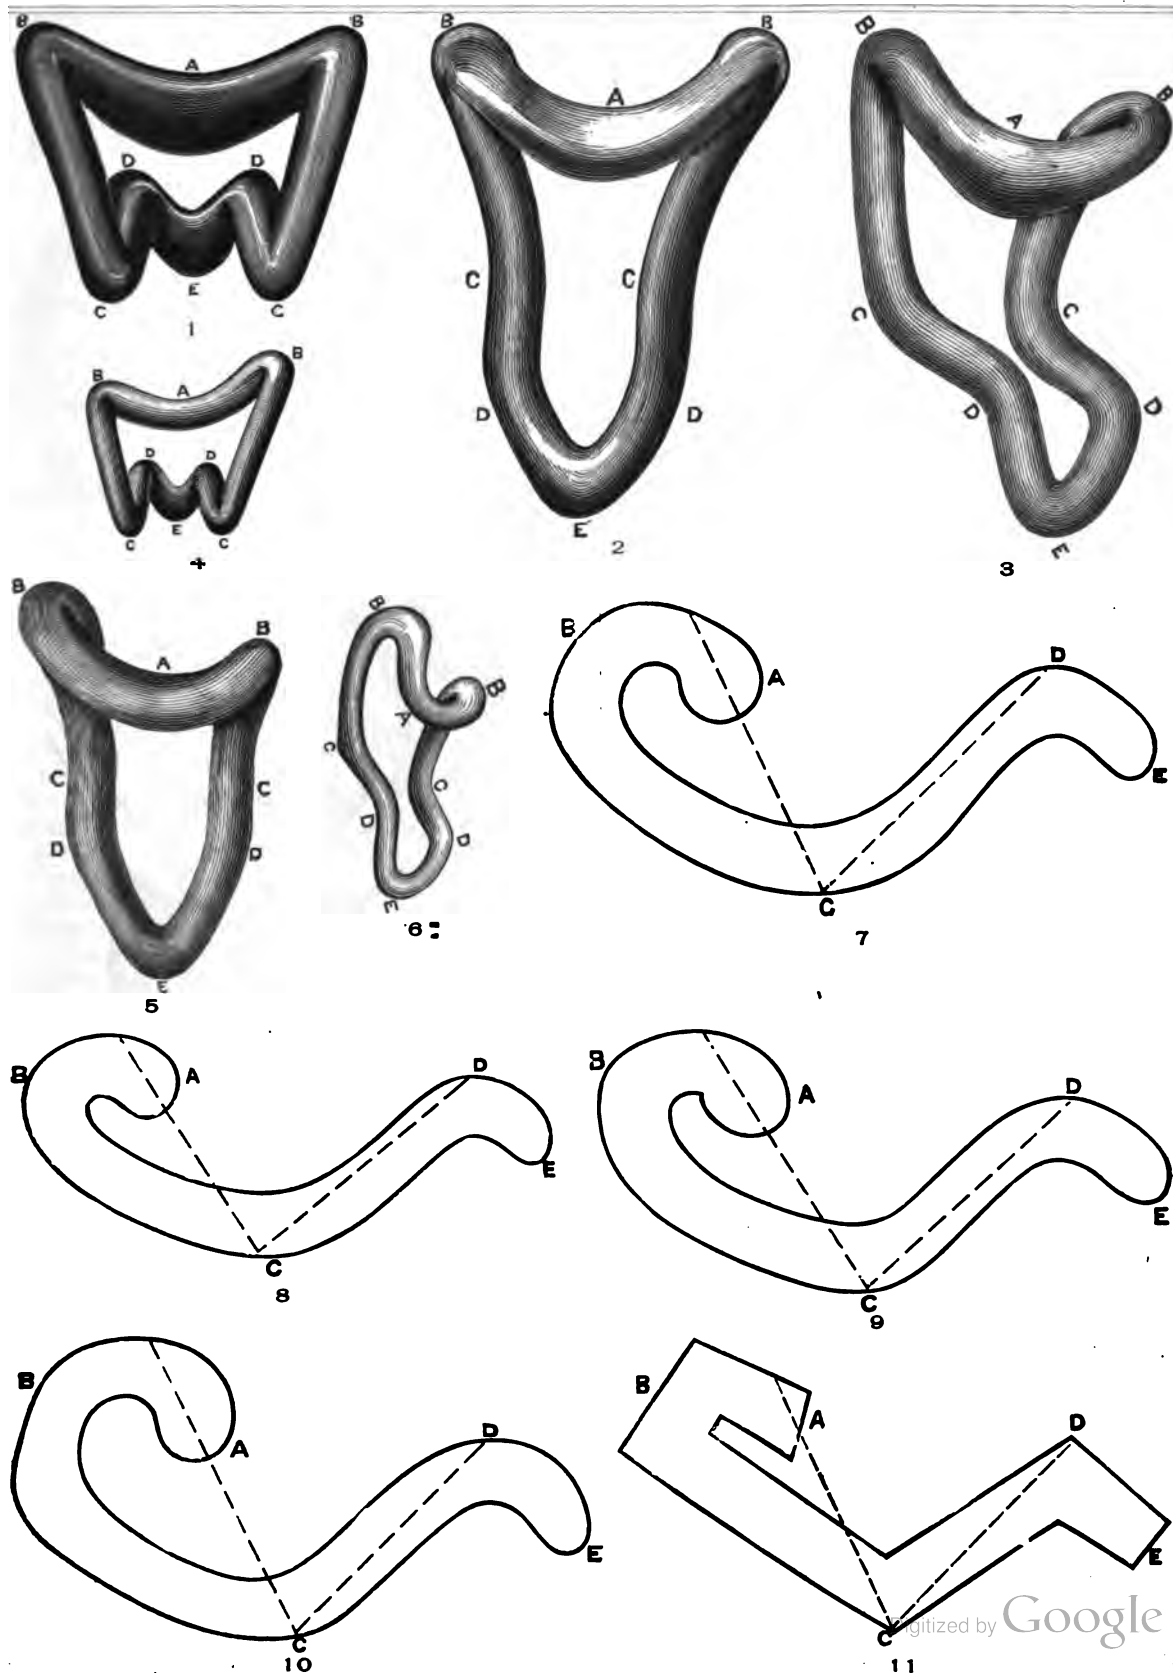

PLATE 1.—a, neck; b, shoulder; c, elbow; d, handle; e, free end; 1, 2, 3, different views of same instrument; 4, 5, 6, modified for lateral displacements; 7, for small vagina; 8, ordinary form; 9, for lax vagina and outlet; 10, for raising heavy uterus from relaxed pelvic floor. 11, schematic.

I have constructed a pessary to take the place of the cotton plugs I formerly used, which I think possesses the virtues of both Courty's and Gehrung's, although it was devised and so far perfected before I had seen or studied either of them. It may almost be made from a Thomas' or Albert Smith shape by bending forward the posterior arms so as to form a sort of crescent running around in front of the cervix and impinging against its anterior and lateral vaginal junction. The uterus settles in this crescent or neck more comfortably than against a cotton plug, and if too heavy for its supports, is held up by the pressure upwards of the neck, or crescent against the vagina around the anterior half of the cervix. The shorter curve of the arms is placed anteriorly instead of posteriorly as in the Hodge patterns, in order to retain the lever action. (Plate 1).

Handle curved up behind symphysis instead of under the pubic arch. For relaxed vaginal outlet.

The parts of the instrument are a neck *a*, two shoulders *b, b*, two elbows *c, c*, two arms *b, c, d, a*, a handle *d, d*, and the tongue, or, free end, *e*. The uterus impinging against its neck at *a* makes a lever of it, whose arms are represented by lines passing from *a* to *c* and *c* to *d*, and which, during ordinary abdominal pressure forces the handle *dd* up behind the symphysis pubis instead of through the vulva. The elbows or fulcrum *c, c*, rest on the posterior wall of the vagina or on the pelvic floor, at either side of the rectum. The longer the arm of the lever *ac* in comparison with *cd* the greater the upward pressure of the handles and the less their liability to escape externally. If during heavy lifting, defecation, or abdominal pressure while in a stooping position, the depressed anterior vaginal wall forces the handle down until it appears under the pubes, the patient has only to push it back; or if (as seldom happens with a properly adjusted pessary) it does not slip into proper place, she has but to assume the knee chest position. This descent of the handle under great pressure, instead of being a disadvantage acts as a sort of safety valve, to prevent injury being done.

On account of slight relaxation of the vagina or of the pelvic floor, it may, when the uterus is unusually heavy, become necessary to change the first instrument for a larger size, or else make some alterations. Later a smaller one may again be used. The alterations most often required are raising or depressing of one or both shoulders, or of the neck, or of both

shoulders and neck, in order to afford more or less general support at different points; or to vary the curves of the arms in order to increase or diminish the lever power. Escape may be effectually prevented by taking off the tongue, making it more like the Courty or like a reversed sleigh pessary. It may then be used for retroflexion and prolapse.

A very small instrument with gentle curves is required for the virgin and congenitally sterile woman, while a very large one with abrupt anterior curves and broad handle may be required for the child-bearing woman with relaxed vagina and pelvic floor. The shoulders must also be higher in proportion to the centre of the neck when the upper vagina is relaxed, so that they may get a vaginal bearing on either side of the cervix. (Plate 2).

PESSARY IN PLACE.

Dotted and interrupted lines show possible temporary positions of the uterus allowed by the pessary.

PLATES 2 AND 4.—R, rectum; P, perineal body; Ur, Urethra; V, vaginal entrance; S, symphysis; B, bladder; a, b, c, d, e, pessary; Ut, uterus; L, lines indicating places for uniting cervix or anterior vaginal walls with posterior vaginal walls.

I have made the pessary fulfil the following six requirements in its own class of cases:

1. To place the uterus in a normal, or nearly normal, position.
2. Not to interfere with the natural supports.
3. To support the uterus in a natural manner; *i.e.*, to afford an elastic or yielding support.
4. Not to interfere with the use of a speculum.
5. Not to interfere with the marital relations.
6. The patient shall be able to both introduce and remove it.

The ordinary Hodge pessary and its modifications are generally faulty in requirements one, two and six. This pessary allows the vagina to collapse, and practically presses against no supports, except the posterior vaginal wall or pelvic floor. Its neck is firmly pressed upon by the cervix uteri only a part of the time, *viz.*, during the action of influences tending to retrovert the uterus; the constant pressure is distributed half-way around the cervix and is against the

PLATE 4.—Median section after operation for raising posterior vaginal wall, perineum and pelvic floor, as a barrier to the forward displacement of the cervix. The section is supposed to swerve to one side of the rectum, to give a better view of the relations of the pelvic floor to the uterus. Rectum indicated by dotted lines. Places for uniting vaginal or cervical and vaginal walls indicated by lines.

vaginal junction. All other instruments of this class fail because they exert constant pressure on the cervix in front and are thus unscientific and intolerable. But perhaps its most valuable characteristic is that it can be properly introduced by the patient. She has but to slip first one of its shoulders under the symphysis, and then the other over and beyond the depressed fourchette, turn it so that the neck will be towards the urethra, and then assume the knee chest position and allow it to slide into place, or she can introduce it while on her side after having replaced the uterus by the knee chest position. In removing it she turns it a little more than a quarter circle, so that one shoulder is toward the symphysis, and then, as she pulls it out, pries either the upper or lower shoulder out under the symphysis, or over the fourchette, as she finds easier. A slight twist or rotary motion as the first shoulder escapes, so as to miss the urethra will enable her, after a few trials, to remove it easily and painlessly. After wearing it steadily for a couple of months she may remove it nights and introduce it mornings for three, four or six months longer, avoiding sleeping on her back. A very practical point here is to caution the patient after removing it not to allow the bladder to become much distended in the night until all tendency to retroversion has been lost. She may either avoid taking fluids in the evening, or else get up and urinate during the night. Carelessness on this point in the treatment of retroversions often delays, and sometimes prevents, a cure.

The pessary may usually be introduced by the physician, in the lithotomy position by following it into the vagina with the finger under the handle, and pressing down, or back, the cervix while the other hand pushes the instrument and uterus into place, or if unsuccessful by putting her into the knee chest position, and displacing the fundus from the hollow of

the sacrum by the finger, when the instrument need only be allowed to follow into place.

Especial contra-indications to this form of pessary are: Tenderness or induration in the vesico-cervical region, decided *retroflexion*, an insufficient projection of the cervix into the vagina, and an unusually short vagina, more particularly the anterior wall. Irritation on either side of the urethra or pressure upon the deep dorsalis clitoridis nerves and vessels are not contra-indications, but call for a greater approximation, separation or downward curving of the arms anteriorly at the handle. All pessaries require some skill in preventing irritations.

Especial indications are: Retroversion with subinvolution after abortion or labor, or with bilateral laceration of the cervix in which the traction of the other forms acts hurtfully, a lax vagina, post cervical tenderness. It is useful after the uterus has been held anteverted by the Hodge instruments for some time and we wish a less rigid support, and one that the patient can use, and gradually lay aside. I find the uterus less apt to retrovert after its prolonged use than after any of the Hodge class.

In preparing a subinvolved uterus with bilateral laceration and eversion, but without retroversion, it is also exceedingly useful in lifting the cervix from the pelvic floor. When properly adjusted it acts as a support to the everted labia us well as to the uterus, and often causes the ulceration to quickly fade out. One shoulder may be enlarged or raised for lateral flexion or inclination, provided no rigid ligaments or adhesions interfere.

As pessaries whose only aim is to relieve the retroversion, the Hodge forms will perhaps answer in more cases, for they hold the uterus anteverted, but as a pessary which interferes the least in most cases for which it answers, and which is suited to its own class better than any other, I find this one of great value.

I hope that it will not be tried by any one for all cases of retroversion, and condemned because of frequent failures. For instance, I have a case of retroversion and anteversion with a long and flabby anterior vaginal wall, in which I failed with this pessary, because the cervix slipped down under the neck if the neck was high, or slipped over it if it was too low. Yet in this case a thicker neck would undoubtedly have remedied the defect. The Albert Smith pessary had been tried twice before, and was not tolerated. The most common of the contra-indications which I have met are the retroflexions which so often co-exist with retroversions. For these cases the bar should be behind the uterus or the Harry Sims form be used, or my pessary combined with a stem.

Among plastic operations I have found the raising up of the recto-vaginal promontory and perineum of great benefit, and sometimes curative. This makes it necessary for the womb to rise in the pelvis before the os can get forward, and thus places a barrier before the cervix, and also tends, by fixing the vaginal walls, to correct its excessive mobility. It is chiefly accomplished by shortening the relaxed or retracted fibres of the levator ani muscles, and including some of the connective tissue with the stitches. The form of denudation must vary with

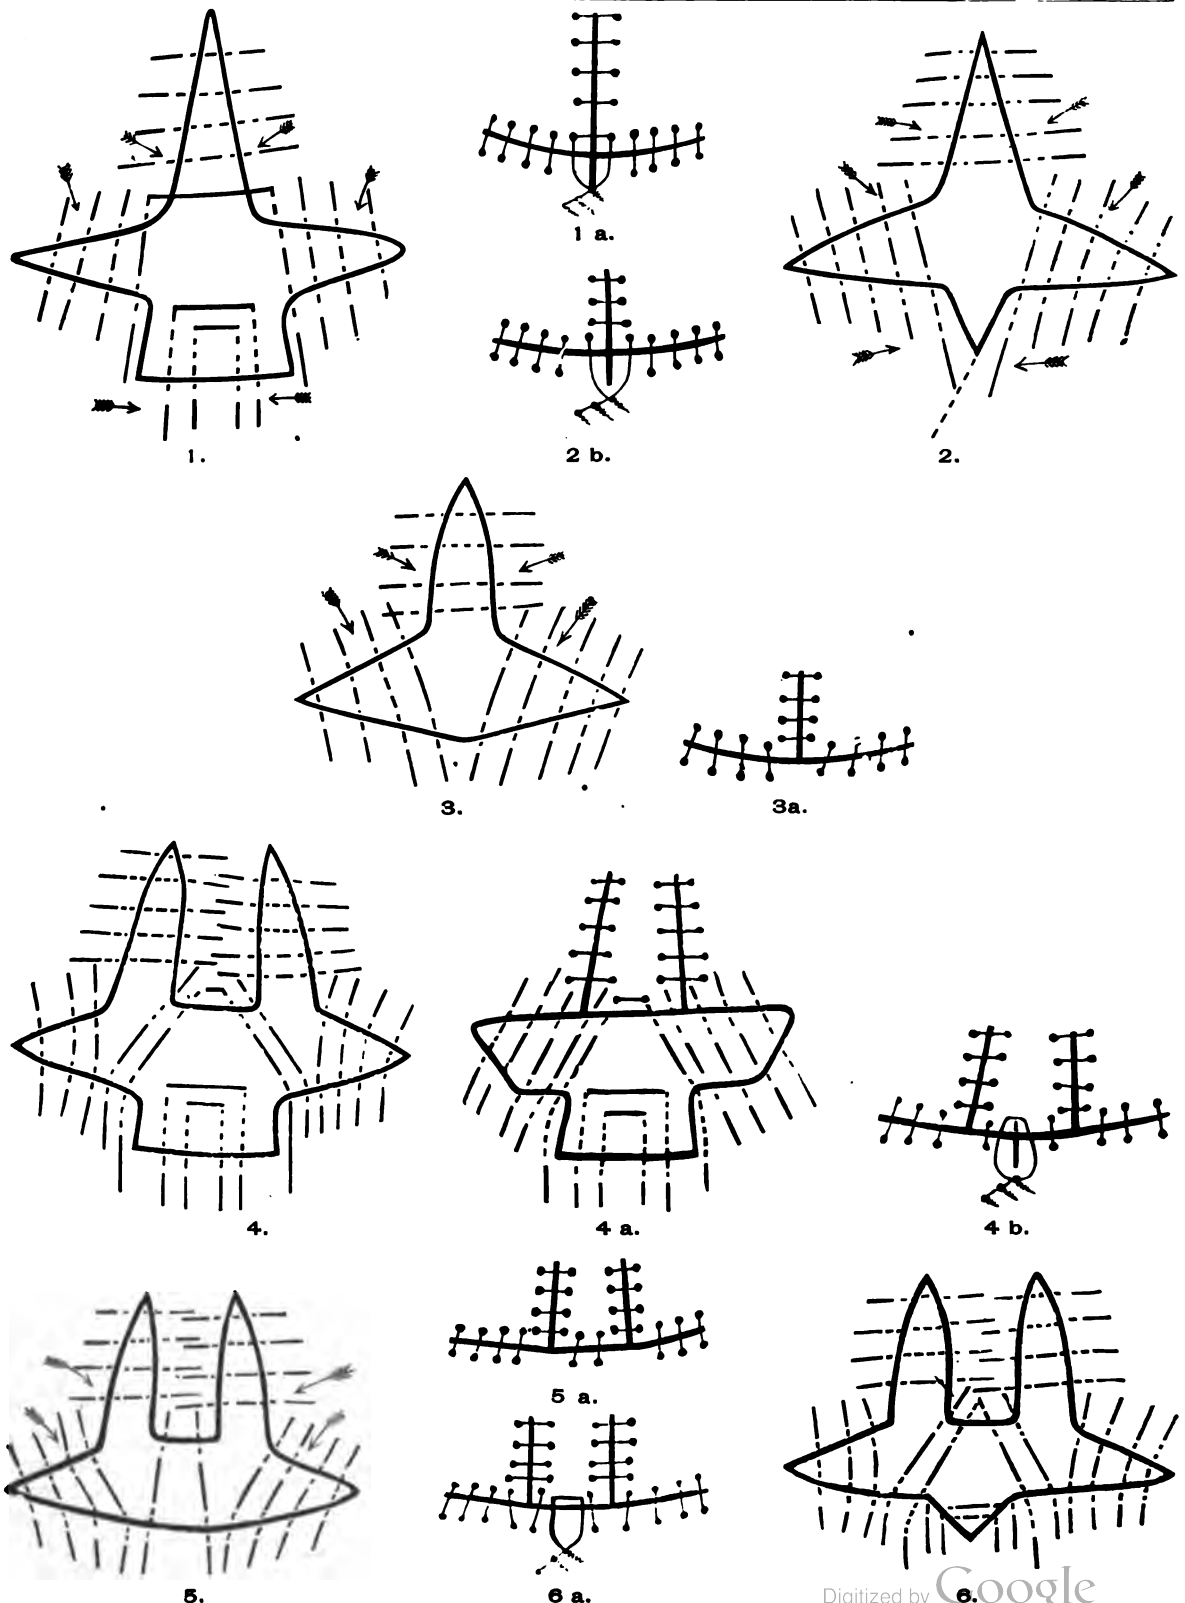

PLATE 3.—1. Complete figure, with central triangle. 1 a. United. 2. With small triangle in vulva, for raising fourchette. 2 a. United. 3. Without narrowing vulva. 3 a. United. 4. Complete figure, with lateral strips posteriorly. 4 a. Posterior strips united. 4 b. United. 5. Without narrowing the vulva. 5 a. United. 6. Triangular notch for raising the fourchette, added. 6 a. United. Arrows show the main directions of muscular fibres. Dotted lines show where the stitches dip into the tissues.

each case. That which I have found most successful is a transverse strip removed just inside of the fourchette or carunculae, between one and two inches long, and from one quarter to an inch wide, crossed by a triangle whose base is at the posterior commissure, or, if that had been destroyed at the junction of skin and mucous membrane or cicatricial surface externally, whose sides pass through or include the lower carunculae, and whose apex is in the median line of the posterior vaginal wall beyond the introitus (Plate 3). An imperfect star is thus produced which contains considerable denuded surface, but whose points or angles, upon being sewed up, will unite ends of muscular fibres without much traction upon other surrounding tissues or displacement of parts. The main stitch, introduced through the right labium majus at the base of the triangle and brought out through the mucous membrane at a point near where the same side of the triangle intersects the posterior border of the transverse denuded strip, then introduced at the corresponding point behind the transverse denuded strip on the left side, and brought out through the left labium at the base of the triangle, will draw the star together in the form of a cross, and indicate what edges are to be stitched together. This main stitch should not be twisted until after the vaginal stitches.

The triangle will, of course, be divided in the centre as the star is pulled together, forming two long right-angled triangles whose shorter legs form the restored cutaneous raphe of the perineum as they meet in the median line. Their hypothenuses coming together in the median line, in the vagina form one side of the cross; the united transverse strip forms the other side. When the patient has not borne children the perineum is seldom greatly relaxed externally and the vulval wedge may be omitted, so that the base of the triangle will be upon the posterior border of the transverse denudation. A small neck or minute triangle may be taken from the fourchette, whose apex is at the posterior commissure, and whose base is at the anterior edge of the transverse strip, to better raise the sagging fourchette. Or if the fourchette be already high, the point at either end of the transverse strip may be placed so that when the triangle projecting into the vagina is closed both sides of the transverse strip will be of equal length and be easily united. Broad strips must, of course, not be taken from the vagina of those who may afterward bear children; but, on the other hand, the triangle should be made broad and long and the transverse strip wide in operating upon those with rectocele or who have passed the menopause, in whom there is often great relaxation, destruction or retraction of tissue.

When the *levator ani* has been torn laterally, or when the fibres which pass under and behind the rectum have become relaxed, it will be better, instead of removing the apex of the triangle in the median line, to remove a strip on either side of the rectum, something like those removed in Freund's operation, and thus draw up deeper fibres of the *levator ani*. They may be removed and sewed up immediately, *i. e.*, before the rest of the figure, as Martin does in

his "*Elytrorrhaphia duplex lateralis*," and may go with all the varieties of the anterior denudations mentioned.

Since becoming accustomed to these forms of denudation I have found it also more convenient to denude the apex of the triangle first and sew it up before denuding the rest of the figure, thus saving the loss of considerable blood. The objection to this consists in the difficulty in knowing, in the beginning, how far up the vagina to carry the denudation.

The transverse denudation is for shortening or re-attaching the fibres of the *levator ani* which pass from the pubic rami forward to the perineal body and lift that body, while the antero-posterior denudations shorten or raise those that pass more directly towards the median line under the vagina and rectum, and thus lift the pelvic floor and posterior vaginal wall (Plate 4). We thus produce the greatest possible effect in raising and strengthening the parts with the least possible loss of tissue. The uniting of separated fascia and fixation of the vagina to its connective tissue is attained at the same time that the muscles are shortened. The transverse strip not only raises the perineum but attaches it to the pelvic floor, on either side of the rectum. The stitches must be passed deep into the sides or edges of the denuded figures, but should not include their middle sections, since that would bind down instead of raising up the parts. When the parts have been previously injured, and are traversed by cicatrices, the form of denudation must, of course, be modified to suit the case, *viz.* : to remove the cicatrices and restore the injured tissues to their natural relations. The operation should be suited to the particular case, and not the case suited to a particular operation. The old notions of building a pyramid which never existed; of constructing a firm triangle in the median line, where a firm triangle must be a pathological condition; of projecting a huge rigid cicatrix between the elastic walls of the rectum and vagina, to run the risk of being gradually melted away by time and traction; or of cutting away, instead of replacing, prolapsed masses, are the crude methods of an age of transition, and continue to live, not as useful remedies, only for want of something better.

If the anterior wall of the vagina be much loosened anterior elytrorrhaphy should also be performed as an important, if not necessary, part of the cure.

The patient, after all plastic operations for retroversion, should be kept in bed, but not be allowed to lie on the back for two weeks. It goes without saying that should such plastic operations be undertaken indiscriminately, failure must be the result. The main part of the cure must be made before this nearly mechanical part, *viz.* : the restoration of natural checks upon the motions, and hindrances to the falling over backwards, of the womb.

To the criticism that I am producing an unnatural state of things by thus elevating the perineum and recto-vaginal promontory, I must answer that I have seen many well developed patients in whom the promontory and portions of the perineum were naturally thus elevated without inconvenience either before or after marriage, and that I am imitating

nature by taking the perineæ of such women as models for the operation.

The anterior vaginal or cervical walls may be stitched to the posterior vaginal walls, as a preliminary or first step in performing the above described operation, if the case be unusually unpromising or complicated, and the patient be beyond childbearing.

The denudations should be made where the walls come together after the uterus has been anteverted and the cervix pushed well back, and need not be as extensive as in the Le Fort operation for prolapse. Occlusion of the vaginal canal must, of course, be avoided.

This brings us to the combination methods. The Alexander operation is nearly always combined with support by a pessary for a few weeks or months. It should often be preceded by a plastic operation either for raising or restoring the perineum and recto-vaginal promontory. Other combinations may be devised, some fanciful and some practical. The posterior cervical and vaginal surfaces may be united and a Harry Sims or Gehrung pessary be used to hold the uterus in place until the union is firm and the tendency to retroversion diminished. The abdominal section operations may be supplemented by plastic operations or pessaries. Both walls of the cervix may be stitched to the posterior vaginal wall, before and behind, or the cervix may be stitched posteriorly and laterally to the vagina.

The Fitch, Studley, Schultze's figure eight, and sleigh pessaries, the Hurd, Fowler, Fritsch and Woodward patterns, Martin's eccentric ring, cotton plugs used as recommended by Thomas, etc., are more or less perfect examples of combined traction behind and support in front. They are indicated when the upper surroundings and supports of the uterus are tender, and motion of the organ is to be limited by a firm hold upon the cervix.

In conclusion it must be said that such mechanical treatment as a routine and sole remedy for retroversion is only exceptionally curative, since the original cause and its accompanying or resulting pathological conditions, if still present, tend to break down all barriers and tear loose all attachments.

MEDICAL PROGRESS.

ALBUMINURIA DEVELOPED EXPERIMENTALLY IN MAN.—SCHREIBER has studied in man the effects produced by compression of the thorax, or of a portion of that cavity, the pressure being exerted by means of cushions applied to the anterior and posterior walls of the chest, and regulated by screws. Among twenty-six people he found twenty in whom the compression developed a temporary albuminuria, or increased a preëxisting albuminuria. In a general way the degree of albuminuria varied with the duration of the compression, while some experiments showed that the daily quantity of urine was slightly diminished under the influence of compression. Most frequently the reaction of the urine was acid or neutral, rarely

alkaline. Microscopic examination was made in only a small number of cases, and once a few hyaline casts, and once a few red blood corpuscles, were found. The albuminuria is due to the presence of serum-albumen and globulin, and peptones are also present. Its duration was one or several hours, all that was needed to prolong it being a repetition of the compression several times in the course of the day. Schreiber does not consider this albuminuria due to dyspnœa. He believes that its causes are: The diminution of the difference which normally exists between the pressure in the capillaries of the alveoli of the lungs and in the left ventricle; the diminution in the calibre of the pulmonary vessels; the diminution of the extent of the respiratory excursions. From these there results a stasis in the pulmonary circulation, which is rapidly propagated into the vascular network of the kidneys, and hence the filtration of albumen. Whether this filtration occurs in the Malpighian corpuscles, or in the convoluted tubules, he has not yet determined.

In a second memoir M. Schreiber states that in boys of 11 to 15 years thoracic compression for half a minute sufficed in eight out of ten cases to provoke albuminuria ($\frac{1}{3}$ to $\frac{1}{2}$ per cent.), of which, in general, there is no trace at the end of an hour. In their case he found neither peptones nor serum-albuminose in the urine, but only serum-albumen and globulin. The ophthalmoscope showed that the albuminuria was accompanied by no modification of the size or of the color of the vessels in the fundus of the eye.—*Revue des Sci. Méd.*, Jan., 1886; *Glasgow Med. Journ.*, May, 1886.

BROMIDIA.—In the April number of the *Edinburgh Medical Journal* J. LINDSAY PORTEOUS, M.D., F.R.C.S., M.R.C.P.Ed., says: "Of late there has been a great influx of new drugs, some of great value, others of little or no use. Where a medical man has an extensive practice, consisting of rural and urban patients, he has ample opportunity of testing the effects of drugs, as the varieties of disease that come under his notice are great; and although his means of watching the actions of drugs are not so good as in hospital practice, yet a good deal can be done if he cares to take a little trouble to 'take notes.' The following is one which has been used for some time by my colleague (Dr. Proudfoot) and myself, and I give the results: About eighteen months ago a friend of mine from America told me of the wonderful effects of a medicine, much used in the States, called *bromidia*. According to the makers, it is composed of chloral hydrate, 15 gr; cannabis indica, $\frac{1}{8}$ gr.; and extract of hyoscyamus, $\frac{1}{8}$ gr. I obtained some, have ordered it regularly for over a year, and have found it excellent in the pain of rheumatism, pneumonia, and cancer; also in the sleeplessness of scarlatina and alcoholism. It has never failed me in procuring sleep, without the disagreeable dreams and after-effects of opium. The dose is 3ss to 3j every hour till sleep is procured. I have also found it of much service in cases of tonsillitis, used as a gargle with glycerin and carbolic acid."—*N. Y. Medical Journal*.

No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, AUGUST 7, 1886.

ARE OUR OBSTETRICAL PRINCIPLES
UNSCIENTIFIC?

It is not infrequent that we read papers based on twenty or twenty-five cases, and even less, in which not only are legitimate conclusions drawn, but in which also something of real value is added to our stock of knowledge. But it must be admitted that there is a wide difference between seeing facts and drawing proper conclusions from them—between observation and generalization. It must also be admitted that one who has a moderate, or even unusual, degree of success in practice should not jump to the conclusion that all those who differ with him both in practice and theory are wrong, and that their practice and theory are unscientific. Yet the literature of science is full of such erroneous deductions.

In some recent numbers of *New York Medical Journal*, is an article by DR. HIRAM CORSON, of Conshohocken, Pa., entitled "The Statistics of Three Thousand and Thirty-six cases of Labor," which was read for the author by Dr. Goodell before the Obstetrical Society of Philadelphia, on April 1, 1886. With such an experience it would be supposed that the author would at least be able to draw certain conclusions which would be of positive value to the young obstetrician, and which would be interesting, if not new, to the teachers of this branch of medicine. Unfortunately the paper is not logically sequential, nor is it rhetorically connected, and for these reasons it is sometimes difficult to follow the thread of the argument. But anyone may follow it sufficiently close to ascertain (?) that while in other branches of medicine marked progress has been made in the past fifty years, we have advanced backwards (so to speak) in obstetrics. We learn that Credé

method of treating the third stage of labor, the teachings as to the value of antiseptics in midwifery, of the treatment of post-partum hæmorrhage, puerperal eclampsia, and the usually acknowledged principles regarding the use of the obstetrical forceps, are not only wrong but absurd, and that the teachers of obstetrics, especially those who have charge of large lying-in hospitals and who write and teach most, are misleading the profession; and we are left to infer that parturition is always the same physiological process, whether the patient be a strong country woman or a delicate and often badly nourished resident of a city.

"Are antiseptic solutions, when thrown into the vagina and uterus, safe?" Such is the question which the author asks, and to which he replies: "I do not know." It is then proper to inquire why he should have taken the trouble to discuss antiseptics to the length of two pages and a half. He tells us that he has never used them in his three thousand and thirty-six cases, and yet, after taking the most extreme views of the advocates and opponents of antiseptic midwifery, he hastens to the conclusion that it (and by it he understands the use of a *one to twenty* solution of carbolic acid!) is dangerous. He assumes a widespread belief on the part of teachers and obstetricians that there is an absolute necessity to practise the rigid rules looking to a *speedy* termination of every stage of labor by *forcible* means; and in view of this assumed belief he asks: Is labor a natural process? To this we may reply with another question: If labor be the natural process which you assume, why is it necessary to call in a physician at all? And we may also ask: Are human beings to-day natural? Is not our whole life, in civilized countries, artificial? "It appears to me that many persons who report the doings of foreign hospitals and urge their adoption here, and know little of its danger, assume a great responsibility, indeed, sometimes imperil the health, if not the lives of those on whom such measures are practised," says Dr. Corson. Yet we have just seen that he has never used these measures which he decries, and which he clearly does not understand. Had he carefully read the statistics of the Rotunda Hospital, and of many other hospitals, and had he seen the article by Dohrn giving the statistics of forty-three public maternity hospitals in Germany, we doubt if he would have written such unmodified sentences.

The precise object of Dr. Corson's semi-polemic against the forceps is not clear. He tells us that he used forceps thirty-one times, though he does not say under what conditions or indications he used them. It was a few years ago that he learned that forceps

were being used more frequently than "twenty years ago, and that this was done in the early part of labor, not because Nature was inadequate to the work, but because the physician had never hurt *himself* by using the instruments," etc. It may be remarked that the usual indications are cases in which the ordinary forces are insufficient to overcome the obstacles to delivery; and cases in which speedy delivery is demanded in the interest of either the mother or child, or both. As regards the imaginary misuse of this instrument, we would recommend a careful reading of the third edition of Emmet's "Principles and Practice of Gynecology," in which the opponent of the instrument will find much to think of. That an unskilled person may do injury with it is not to be questioned; but the same is true of the catheter. And we would quote the following from Lusk's masterly work: "It will be seen that forceps is not alone indicated in the presence of perils fully developed, but is of still greater service as a prophylactic against the dangers of an unruly second stage." It is not wise in the exuberance of sarcasm to make unscientific statements: if our author has learned that forceps are used in the early part of labor (by which he probably means their use at the brim of the pelvis) because the physician had never hurt himself, or because he had another engagement, he has received instruction from a very unwise teacher.

The section on Credé's method of expressing the placenta reads as though it were intended for the exaggeration of pleasantry, and is none the less amusing even if we know that it was not so intended. So far as we have been able to discover the learned promulgator of this method of placental expression says nothing about "pouncing" upon the woman and pressing the womb to the bottom of the pelvis, as Dr. Corson would have us believe, nor does he advance the rather original idea that the hollow of the hand can make a dent in the uterus through the abdominal walls, and thus *push out* the placenta. It is possible to carry out this method to the letter without "pushing the womb down to the very perinæum." Those who are conversant with the method know that Credé lays very great stress on the *avoidance* of violence in the practice of his method. Where, then, did Dr. Corson get his ideas of the method? Should he care to inform himself fully on this subject we would call his attention to an article in the April, 1885, number of the *American Journal of Obstetrics*, in which Dr. Baruch very clearly points out the mistaken ideas as to this method. To the untaught teachers of modern midwifery it seems to have certain advantages over waiting half an hour for a quarter

of a grain of morphine (internally) to act in a case of hour-glass contraction.

Before the advent of the faith-cure it would have been difficult to fully understand how the imagination of a parturient woman could prevent or suppress *post-partum* hæmorrhage; and it is almost as difficult to understand now. Perhaps, however, it is because few physicians have the power of exercising that effect on the mind which, transmitted to the blood-vessels, will cause a contraction of the vascular walls, and thus a cessation of hæmorrhage. Be this as it may, very many practitioners of obstetrics, even before they have delivered three *hundred* women, do encounter cases of serious and alarming hæmorrhage, controllable neither by laying the hand on the abdomen, giving ergot, nor by stimulation of the imagination and excitation of faith. But here again, we are told that Dr. Corson has never had a case of alarming hæmorrhage in his practice; so that we may well inquire if a "confident, assuring manner in the physician" would be so potent if one did occur in his practice?

If the author's success in the treatment of puerperal eclampsia has been somewhat phenomenal, his ideas as to its pathology may certainly be considered unique. Temporarily accepting the uræmic theory, and supposing that there is a certain amount of urea in the blood which is poisonous, he would resort to venesection, and "remove with the blood so much of the urea that the remainder could not exercise a toxic effect sufficient to produce convulsions." Among his three thousand and more cases he had only ten cases of puerperal convulsions, all of which recovered. The treatment which he recommends for puerperal eclampsia is that upon which a small book was written about three years ago, by Dr. Ezra Mechner, of Pennsylvania—free venesection; to which Dr. Corson adds the pouring of cold water over the head, and the use of morphine internally. While there can be no doubt that venesection is positively indicated in some cases of puerperal eclampsia, we fear that one who resorts to it too frequently is possibly unacquainted with the use of morphine hypodermatically, especially when he uses this drug internally. It is to be questioned if modern teachers, however Teutonic they may be, will agree with him in saying: Suppose it to be true that a certain amount of urea in the blood is poisonous, venesection would then be my remedy. Puerperal fever and septicæmic fever he has never seen, and he remarks that if puerperal fever is a disease "different from peritonitis I know nothing of it."

It is with sincere regret that we have found it

necessary to notice this somewhat remarkable paper at such length? but when it is taken into consideration that it was read before one of the most prominent obstetrical societies in the country without a remonstrance on the part of the members, that it has been published in a prominent medical journal, will go abroad, and may be accepted in Europe as a typical American paper, we feel it our duty to enter a protest. What, for example, will be Credé's idea of American obstetrics and obstetricians should he chance to read the description of his method of placental expression? We can only hope that the paper will escape the notice of such men as Carl Braun, Tarnier, Duncan, Felsenreich, Schauta, Pajot, Berry Hart, Playfair, Lombe Atthill, Champneys, and one or two hundred other obstetricians.

Since writing the above we have found in the *New York Medical Monthly* of July, 1886, a paper by Dr. H. C. COE, of New York, in which he has taken the same ground as the foregoing. We are glad to see that the attention of a scientific obstetrician and pathologist has been drawn to the paper, and it still further pleases us that we have the endorsement of Dr. Coe. He concludes his paper as follows: "We are happy to say that, so far as our inquiries have extended, Dr. Corson's opinions are *not* those of the men who endeavor to keep abreast of modern thought. Unfortunately, foreign readers may not understand this, and thus the profession as a whole will be charged with holding views which do small credit to our present enlightenment."

NEWSPAPER REMEDIES AND THE PUBLIC.

About a week ago a newspaper in this city published a sensational account of the alleged marvelous results of the treatment of diphtheria with spirits of turpentine. The dose for adults was given as a tablespoonful, and for children a teaspoonful, to be repeated several times during the day. That article has borne its legitimate fruit. One child has been placed in imminent danger of its life from the action of the turpentine on the kidneys, and an old woman has been made sick enough to regret she took the advice of the paper. There was no diphtheria in either case, though such was the diagnosis of an officious ignoramus, and turpentine was used solely on the recommendation of the newspaper. The article in question was given a prominent place in the paper, and one or two days afterwards the same paper contained the statement of a druggist that dangerous results might follow the use of turpentine; but this

correction was placed in an out-of-the-way portion of the paper, and no prominence given to the fact.

This is not the first time that innocent and ignorant people have suffered from a misplaced confidence in the stupidity of newspapers. It is very common for papers to give marvelous accounts of cures effected by improbable and dangerous methods of treatment, without pointing out that the methods are dangerous, and proving the assertions by foolish letters which assure the reader that the doctors were mistaken in the cases, and finally gave the patients up. The legitimate sphere of a newspaper is to give the news, revised and "doctored" to suit the varying tastes of their readers, and to print scandals which are unfit to go into the homes of decent people. But while improving the morals of the community they have no right to endanger the health of any one, for by doing this they interfere with the quacks who contribute so largely to their support. Simply as a matter of business, therefore, they should endeavor to sin no more in this manner. Could the person who clipped that article have been made to take all the turpentine swallowed by the woman and child he would probably not be in such haste to give medical advice again. It was an offense against public health, though unfortunately it cannot be reached by the law.

The average reader places a great deal of confidence in the newspaper; the more so when his education is practically limited to an ability to read. And the average man is by no means chary of taking all manner of risks with his life and health, for the cure of imaginary complaints. It is somewhat inconsistent for a newspaper to talk about the dangers of impure water in one column and advise people to take poison in the next, and that too on an assumed diagnosis. It is not always that a physician can diagnose *the* disease when he first sees the patient; and other people can't be expected to do better than this. There is something very mysterious about the amount of medical knowledge possessed by old women, uneducated people generally—and journalists. It is an especially noticeable fact that the more ignorant a person, and the less common sense he has, the more infallible remedies he can recommend. Could they be induced to take all their remedies at one sitting the country would probably be less populous, but it would be better off.

CHOLERA MORTALITY IN 1885.—It is reliably estimated that not less than 100,000 deaths were caused in Spain by cholera last summer, more than 2,000 in France, and over 4,000 in Italy and its provinces.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

*Stated Meeting, July 6, 1886.*THE PRESIDENT, E. J. DOERING, M.D.,
IN THE CHAIR.

DR. CHARLES T. PARKES reported a case of

- (a) URINARY FISTULA OF 12 YEARS' STANDING, FROM GUNSHOT WOUND, WITH SPECIMEN.
- (b) THIRTY POUND MULTILOCULAR OVARIAN CYST, JELLY CONTENTS, WITH SPECIMEN.
- (c) LAPAROTOMY FOR MULTIPLE HYDATIDS OF THE ABDOMEN, WITH SPECIMEN.

In regard to the first case, the track of the bullet had been such that the urine could escape through the wound on the thigh. Several unsuccessful attempts had been made to close the fistula. While examining the bladder with a sound Dr. Parkes discovered a stone. Lithotomy was performed, and now the patient urinates per urethram, and the fistula is closing. The calculus was size of pullet's egg, and the nucleus consisted of a piece of bone. Dr. Parkes also exhibited a thirty pound multilocular ovarian cyst with jelly contents, which had been removed without enlarging original incision. He also exhibited specimens of hydatids of abdomen, connected with liver, spleen and intestines. Exploratory operation had been made, but the hydatids were so numerous, large and adherent that they could not be removed. Patient died of exhaustion. Hydatid of spleen measured 23 inches in circumference.

DR. W. T. BELFIELD said: The case in which I am particularly interested is the one in which the stone was found in the bladder. I congratulate Dr. Parkes on his discovery of that stone, because the case had been a reproach to surgery for twenty years. I once saw the patient who was kind enough to perform for my benefit, and threw a stream some little distance through the fistula in the thigh. Probably the stone was overlooked from the fact that it was situated pretty high up, attached to the upper wall of the bladder. I recently had a case in which stones weighing $2\frac{1}{2}$ ounces had been carried by the man for eight years; he had been sounded a number of times, once under chloroform, but with negative result every time. In that case I found one of the stones attached to the fundus of the bladder, the other ensconced behind an enlarged prostate.

DR. R. G. BOGUE said: Mr. President, the cases presented are of a great deal of interest. Probably the most interesting feature of the case of stone in the bladder was the discovery of the offending body and its removal. The strange paths that bullets take in their course through the body, or a portion of it, were found to be so various by those who have had opportunities for observation during the war, that the fact of this bullet passing into the side of the thigh, wounding the bladder and passing out through the peritoneum, was not so very strange; but the repair which took place in the track of the bullet, the lodg-

ment of the large fragment of bone such as we see here, within the bladder where it remained for so long a time without giving a great deal of trouble, is somewhat singular, and the long experience that the man had in seeking relief, or cure, without avail, and the probably accidental discovery of the real difficulty and the cure by removal of the stone, renders the case one of a good deal of interest. The case of hydatid cysts is also of much interest. Hydatid cysts are comparatively rare, although in hospitals where a great many post-mortems are made they are frequently found; in many instances they give so little trouble during their growth that they are only found upon post-mortem examination as an accidental affair, the liver being the seat of the great proportion of instances of their development. In looking over the first volume of the catalogue of the museum of St. George's Hospital, of London, I find that there are eighteen specimens of hydatid cysts mentioned, one of the lungs in a lad who had had chronic cough for some two years, subsided after he had expectorated anhydatid cyst. All the other hydatids developed from the liver; one was a case of multiple cyst where a large cyst had developed upon the superior surface of the liver causing absorption of the diaphragm, entering the thoracic cavity and becoming adherent to the right lung; the abdomen was quite filled with tumors attached to the omentum, the spleen, the kidney, and the under surface of the liver and some to the peritoneal surfaces. In this case there had been, no doubt, a ruptured cyst, as the young man had fallen while at play and the accident was followed by severe symptoms of prostration or collapse, with recognized peritonitis, from which he finally recovered, but afterwards died of erysipelas. The tumors in the abdomen had been diagnosed some two years previously, but the death was from cause other than that connected with the growths themselves, and the revelation upon post-mortem was that of extensive hydatid disease, the greater part being connected with the liver. All of the other instances of hydatids were of the abdomen, connected with some portion of the liver, either within the organ or upon its surface, so that in all of these eighteen cases the specimens were from the liver or within the abdomen, having the liver for their primary seat, with the exception of the one in the lung.

DR. J. S. JEWELL said he had been deeply interested in listening to the cases reported by Dr. Parkes, but most especially in the cases of urinary fistula. He thought in such cases as stone in the bladder, as well as all others, there should be the most thorough and careful investigation. When one undertakes to explore the bladder for stone, cases like this ought to be held in mind. He suspected that in the case in question Dr. Parkes was pretty nearly giving up the examination with the sound when he made the last sweep that brought the stone to light. He was impressed with the necessity for more thorough work than is usually given in the matter of diagnosis. He was becoming more careful every day, as a matter of habit and duty. In studying cases, apparently the most simple, one of ten finds, where they least suspect it, remarkable things. He thought there was

too much hap-hazard diagnosis to produce first-class work, and this case is an example of it, for if Dr. Parkes could find the stone, others should have done so.

DR. C. T. PARKES in closing the discussion said, Dr. Jewell is correct in his supposition, that it was by a mere accident that I found this stone. Perhaps I neglected to say there is no tissue in the body that is free from this parasite; there are only certain places in the body where it is found with the absence of an adventitious sac, but some, especially those found in the brain, are usually cysts with but two layers, the terminal membrane and the external layer. There are many things that seem to refer their formation and development to the circulation of the blood cells through the blood, and there are many things that seem to show that this cannot be possible.

DR. HENRY T. BYFORD read a paper entitled

THE MECHANICAL TREATMENT OF RETROFLEXION OF THE UTERUS.

(See page 147.)

DR. H. P. MERRIMAN said: I have been very much interested in the paper, which I think is a valuable one. It seems to deal not merely with the subject of pessaries, but with the various means of support in the case of retroversion. I think a great many physicians, when they find a retroversion, without stopping to consider its cause, at once feel that it is necessary to employ a pessary, and in a great majority of instances the use is followed by failure to cure. We all know that retroversion of the uterus has more than one cause; it is due in a great many cases to pressure from above, to weight within the uterus itself, as in the case of a fibroid tumor; the use of the pessary in these cases is of no value—it is only when there has been a weakening of the supports. In the case of weakened ligaments the pessary is of value as a temporary expedient. When the retroversion is due to a weakened vaginal support, which is true in the great majority of cases, for when we find the perineum ruptured, even partially, we are going to have, sooner or later, a retroversion. We find pessaries valuable in these cases, though, as a rule, we should not depend upon them permanently, because we need to restore the vaginal supports by some kind of operation, such an operation as restoring the perineum and curing a rectocele or cystocele, or by the general operative procedures Dr. Byford has mentioned. It strikes me that what we need in nearly every case is to examine the vagina and restore it to its proper shape and position. The uterus is retroverted because the vaginal support is gone, the wall of the vagina has become relaxed and is letting down the uterus, and we want to restore that wall of the vagina. If there has been a ruptured perineum you must restore the perineum, if there has not been we may be able to restore the uterus, and by keeping it in place for six months or a year regain the support of the rested vagina. This will be done in a little different way from what Dr. Byford has suggested. We have got to fit something to the vagina that will extend the posterior wall and push up the cul-de-sac back of the uterus. We cannot do that where there is tenderness, or where there is

a tumor; but where there is not, and it is merely a simple retroversion, then it will be necessary to fit the pessary to the vagina and have it fit in such a way as to elongate and support the vagina in a natural shape. It always distresses me when I hear men speak of fitting a pessary to the uterus. I do not believe it should be fitted to the uterus. It should be fitted to the vagina; the object is to restore the vagina to its natural position, and we must choose a pessary especially adapted for that purpose, and it should lie easily in the vagina.

DR. WILLIAM BYFORD said: Mr. President, I came here with the determination of not speaking upon this subject to-night, because the scope of the paper is so great that if I were to undertake to comment upon half the points it would take too long. I believe the principles of the paper are correct for the treatment of this form of displacement of the uterus, especially the one of acting upon the cervix. My impression is that in retroversion of the uterus there is stretching of the utero-sacral ligaments until they are relaxed, and we find connected with it relaxation of the vagina, which I think is more frequently the consequence than the cause.

DR. FRANKLIN H. MARTIN asked Dr. Byford what advantages he claims for his pessary over the German sleigh pessary? If the fulcrum of this pessary is as indicated in the large diagram, situated at a low point on the posterior vaginal wall, how is he going to get any support for his fulcrum in a case of lacerated perineum? His illustration represents the fulcrum resting very low in the vagina, and it would have no support if the perineum is even partially lacerated.

DR. T. D. FITCH said: Dr. Merriman thinks supports for the uterus are abused. I think so also; they are abused because practitioners do not take the trouble to enlighten themselves with regard to the use of these mechanical supports, but when they get a case that requires a mechanical support they go ahead thoughtlessly to adjust a pessary of the latest device to support a displaced uterus. If from different causes the uterus has become displaced, do not the uterine ligaments become weakened as the result of that displacement? You never have a case of displacement that the uterine supports do not become weakened and relaxed, and can you tone up a muscle or a ligament that is placed upon the stretch to its utmost capacity, by any means, while in this tense condition? It is impossible. We must assist those ligaments to regain their tone by these mechanical supports, relax the ligaments, give them rest, and then by local and general treatment give them tonicity. Having done this you can remove your artificial supports. I fully endorse what Dr. Merriman says with regard to fitting the pessary to the uterus. The pessary should conform to the normal form of the vagina, and that is why we have to have this flexible material so that we can bend them by heat and make them fit the different shaped vaginae. I do not approve, as a rule, of the principle of leverage. And that is why so many physicians fail in the use of Hodge's pessary; the leverage is too great. The pressure is so great in using this leverage that abrasion occurs, and laceration and cutting through the

tissues. Pessaries should never be fitted in such a way as to produce abrasion, laceration or cutting through the tissues. They should not press hard; they should distend the vagina to its normal length, especially, not its normal breadth, and this can be done without much pressure where the uterus is replaced so the fundus falls forward so as to be in front of the transverse axis of the uterus at the junction of the cervix with the body. If it is thoroughly replaced, then you do not get much pressure when you introduce the pessary. It requires little force to hold the cervix back, and I believe in the majority of cases that here is where the general practitioner fails, viz.: in getting the fundus thoroughly forward, and uterus replaced. Many times it is half raised up and the pessary presses against the body of the uterus so hard that it will imbed its whole thickness in the body of the uterus, producing inflammation.

I have frequently held the sound in the uterus and held the uterus up thoroughly anteverted, or thoroughly at right angles with the vagina and introduced the pessary over the sound so as to secure thorough replacement of the uterus. I believe in the use of the pessary not only as a support to the uterus, but as a splint to the vagina, for if the vagina is kept in its normal position the uterus will necessarily be kept in its natural position. The ideal pessary, in my opinion, is the pessary of Hodge. Emmett's pessary will fit more vaginas than Hodge's or Smith's, the latter differing from Hodge's in that its vulval extremity is narrow instead of broad, Hodge's is broad while Smith's and Emmett's are both narrow at the lower extremity and are supported by the walls of the vagina. Emmett's is much better than Smith's, is much larger, and therefore much less liable to press too hard upon tissues. The pessary of Dr. Byford which he has introduced to-night, is the form which I have improvised extemporaneously for myself, and used in several cases. I had six cases where the tissues in the posterior vaginal junction were so sensitive that it was impossible to use a Hodge, Smith, or Emmett. So I took the ordinary pessary of Hodge or Smith, and bent it in the form of a Byford pessary, and found I could use it where I could not use the others. There is an objection to placing this pressure upon the anterior surface of the cervix with a firm unyielding instrument, and I don't believe that Dr. Byford's pessary will entirely remove that difficulty. He has stated in his paper that there is in a great many cases an absence of the anterior lip of the cervix uteri; there is not sufficient of it to be received on this instrument and to be held, its slips off and down in front of the instrument. This is not the only objection, I have found that while the pressure is brought upon the anterior surface of the cervix by the edges on my instrument, it so interferes with the circulation that the anterior lip will become swollen and oedematous. In his instrument there is no ring for the cervix to become imprisoned upon, this is certainly a thing most to be desired where there is an ulceration or laceration existing. If the pressure could be divided between the posterior vaginal junction and the anterior surface of the cervix, the oedema would be much less than where the whole uterus was held

up by the pessary. These pessaries, Byford's and mine, are certainly very strongly indicated in cases where there is great tenderness in the cul-de-sac. A prolapsed ovary with a retroverted uterus may fall down into the cul-de-sac of Douglass and no pressure can be borne there at all, and in such cases the only pessary that can be used with success is one that brings the pressure to bear upon the anterior surface of the cervix uteri.

DR. SARAH H. STEVENSON said, I would like to ask how to treat cases in which the fundus lies high and in which the pressure upon the surface has no effect whatever. Where the fundus is low there is no difficulty. It is very easy to cure that sort of retroversion, but where the fundus is high I do not know how to treat the case.

DR. HENRY T. BYFORD said in closing this discussion, I think it is wrong to say that pessaries are fitted to the vagina; they may be fitted either to the vagina, uterus, or pelvic floor, or all three. In regard to the bearing of this instrument, it forms almost a semi-circle in which the cervix fits loosely and does not get directly pressed upon. It also makes a good support for a uterus that is not retroverted, but which rests on the pelvic floor. I have a case of bilateral laceration with eversion to the third degree, in which after this pessary was applied to the extensive ulceration due to friction upon the pelvic floor, got well in three weeks. I have a case of fibroid tumor in which the uterus lay directly across the pelvic, the right horn on a level with the cervix, but which is held about straight by this pessary modified by having one shoulder lifted, thus giving the patient back her former comfort. In regard to Dr. Martin's question—in the case of laceration just mentioned the levator vaginae portion of the levator ani seem ruptured or relaxed, and leaves a large vaginal outlet, and yet a good sized instrument is retained. A large instrument is of course required for a large uterus or a relaxed vagina. You can change the position of the fulcrum by changing the curve of the arms. The sleigh pessary if reversed looks very much like this one with the handle cut off, but it would require a change in the curve of the arms, and in the neck, before it could be similarly used. My pessary comes the nearest being a perfect representation of one of Dr. Fitch's instruments, which he devised before he became sick, but has not exhibited until to-night, and which is a modified Courty's. About the operation, I would like to say that my object in performing it is merely to raise the natural tissues, not to build an artificial support or barrier of fanciful shape; not to remove any more tissue than is absolutely necessary, but to draw the tissues together as much as is possible or desirable. What I have tried to do has been to find the directions of the muscular fibres and shorten them a little, and if they have been torn to reunite them as they were originally. At the same time I have always in mind the gathering up of the loosened connective tissue about the denudation, and I sometimes cut a little deeper at certain points in order to cut into it and make a closer union of tissues.

AMERICAN OTOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at the Pequot House, New London, Conn., July 20, 1886.

The Society was called to order by the PRESIDENT, J. S. PROUT, M.D., of Brooklyn.

Dr. Friedenburg and Dr. Bartoletti were invited to take part in the proceedings of the Society.

DR. SAMUEL SEXTON, of New York, read a paper entitled

ACUTE AND CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT AND THEIR COMPLICATIONS.

The paper was based on the records of 2366 cases. These cases were divisible into three classes: Acute, purulent inflammation of the middle ear (739 cases), acute catarrhal inflammation of the middle ear (245 cases), and chronic purulent inflammation (1382 cases). The consideration of acute catarrhal inflammation was included in the consideration of acute purulent inflammation, since in the beginning the conditions were probably the same, although not always going on to suppuration. Out of this series of cases 131 were selected on account of their gravity. Of this number there were twelve deaths. In no disease of man is a knowledge of regional anatomy more important than in diseases of the middle ear. The speaker gave a thorough resumé of the anatomy of the temporal bone, accepting the description of Prof. Leidy as the most satisfactory. The temporal bone at birth is peculiar in the fact that the tympanum and mastoid antrum are about as large as they ever become in adult life. The petroso-squamosal suture is imperfectly closed.

The symptoms were next referred to. Brain symptoms, such as headache, vertigo, pain, delirium, nausea and vomiting may occur in consequence of middle ear disease without lesion of the cerebral structure.

The prognosis of purulent inflammation of the middle ear is favorable when non-meddlesome treatment is adopted, both as regards life and the preservation of hearing. Out of twenty thousand cases of ear disease, where the patient has been seen at the beginning of the attack, no fatal case has occurred. Cases which have come under observation after severe symptoms have appeared, have given twelve deaths. Some of the fatal cases occurred long after the ear trouble had abated.

In regard to treatment, the speaker recommended incision of the drum-head. Trephining of the mastoid process has been recommended by some authorities. Dr. Sexton took up a consideration of the indications which have been regarded as calling for the application of the trephine, and held that they were insufficient. From his experience, he was led to believe that drainage could be best maintained through the natural channel.

DR. SEXTON also described a

NEW OPERATION FOR THE RADICAL CURE OF A PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT.

Since describing a form of chronic purulent inflammation of the attic, in a paper read before the Society last year, it had occurred to him that some-

thing might be done with these cases by means of an operation. It seems especially desirable to cure these cases, when the ear remains simply a reservoir for purulent matter, liable at all times to infect the system. It is found that in the greater number of these cases the remaining portion of the conducting mechanism no longer serves to aid in the transmission of sound, but acts rather as an obstruction to drainage. Where the membrana flaccida and a portion of the ossicular chain only remain, the former often becomes thickened and everted, forming, with the altered mucous membrane, a pouch for the retention of putrescent matters which may slowly escape. Where granulation tissue or polypoid growths are present in the attic or antrum, the escape of secretions is still further interfered with. This produces long-continued and great irritation.

The author had observed that in a number of cases where the transmitting mechanism has been lost a cure followed, and it occurred to him that the curative action of nature might be imitated with advantage. Where drainage from the attic and antrum is interrupted a cure can only be assured by an operation permanently clearing the passage outward from the tympanum.

Last year the operation was tried on a long-standing case of otorrhœa due to chronic purulent inflammation of the attic. In order to avoid the danger of using an ordinary lamp in connection with the administration of ether, an electric light was used. The operation has since then been fully performed in several cases.

The first step of the procedure is to separate the membrana flaccida from the edge of the auditory plate, and to remove any portion of the membrana vibrans adherent to the auditory ring. If the malleus and incus remain *in situ*, it is well to divide the tendon of the tensor tympani muscle when present, where it leaves the handle just behind the short process and below the chorda tympani. The chorda tympani, when remaining, is then divided where it enters the tympanum at the pyramid, and also at its exit into the canal of Hugier. The long process of the malleus, being also received into the glenoid fissure by means of this short oblique canal, along with the chorda, may be more or less detached at the same time. The detached tissues and ossicles should now be removed with the forceps. It will frequently be found that the incus, having been displaced, still remains. It may be removed with the attic scraper, which is to be introduced from below and passed up along the inner wall of the tympanum, when the distal extremity may be carried over the incus or malleus, if the latter bone remains, and by traction the ossicles can be detached; polypoid masses, granulation tissue, and the products of inflammation may now be removed with the cutting curette or cutting forceps, and the parts dressed with a four per cent. solution of cocaine to relieve pain.

There is usually free bleeding during the operation, often sufficient to protract it and increase its difficulties.

The effect of injury or destruction of the chorda tympani nearly always manifests itself in some way,

but had never in his experience been a matter of serious import. Disturbances of taste sometimes follow the operation, but they gradually disappear and leave the sense of tasted unaffected.

The drum should be kept well cleansed and light dressings of boracic acid applied until healing takes place. The salicylic acid powder may be applied as freely as can be borne. In some cases this is irritating at first, but tolerance is soon established. It may then be kept up until the parts cease to discharge.

In the cure resulting from this treatment, a dermic transformation of the tympanum takes place, but mucus may occasionally gain admission from the Eustachian tube during recurrent head catarrh or on blowing the nose. This should be frequently removed with cotton wool, and if necessary the drying applications renewed for a time.

Where the incuso-stapedial connection remains, I should not hesitate to perform this operation, unless a very considerable portion of the membrana vibrans was present.

The instruments employed and some of the diseased ossicles removed, were exhibited.

DR. C. R. AGNEW, of New York, said: Where the inflammation has come to involve the mastoid cells, I think that some portion of the external wall of the mastoid should be removed. The objection to the trephine is that it does not expose a sufficient area of the cancellated tissue of the mastoid. I do not see how the new operation which has been described will be of service in these cases.

DR. SEXTON: The new operation I recommended only in chronic cases.

DR. H. KNAPP, of New York: The upper tympanic pneumatic cells resemble, to a certain degree, the frontal sinuses. These have a direct natural drainage through the infundibulum into the nose. When this is closed by disease, the lateral part of the sinus over the orbit dilates and the cavity is more easily reached and more effective drainage is obtained by opening the sinus from the orbit. In a like manner, we obtain in most cases easier and more effective drainage of the supra-tympanic cells by opening the mastoid cells with which they communicate.

DR. A. H. BUCK, of New York, read a paper on
**PAINLESS AND ONLY SLIGHTLY PAINFUL ULCERATION
OF THE MEMBRANA TYMPANI, PROBABLY OF
TUBERCULAR NATURE.**

The speaker stated that the recognition of the early stages of tubercular disease was important, and the object of the paper was to call attention to the features by which this could be recognized. Three cases had been seen by the author. The patients were in a condition of fair general health. There was no evidence of pulmonary disease in either of the three cases. Tinnitus and slight impairment of hearing were the first symptoms noticed. In two of the cases, which were examined at an early period, there was slight redness and swelling at the upper part of the membrana tympani and of the skin covering the bony wall. In a short time the infiltration extended into the entire posterior superior quadrant. The membrane became bulging, and at the most prominent point a perforation established itself.

Following this the disease followed a somewhat different course in the different cases. In one case the upper posterior portion of the canal became more congested, as though the bone were the seat of the disease. In the last case there was gradual improvement. The hearing was slightly impaired. In the other two cases discharge became profuse. In one case sudden hæmorrhage from the lungs occurred.

In the incipient stage, the distinguishing features are the tendency to localization in the upper posterior portion of the membrana tympani, the marked insignificance of the pain or even its entire absence, and intolerance to all but the simplest local measures.

DR. E. GREUNING, of New York: I have seen a number of cases in which I was led to infer that the ulceration of the drum-head was due to tuberculosis. I distinctly recall three cases. In one case, that of a young man, only one ear was affected. There was very little purulent discharge. There were two openings, showing that this was not the result of perforation from accumulation. It appeared to be a melting down process. In another case there were multiple openings so that the membrane appeared to be honeycombed.

DR. C. R. AGNEW: I have seen a number of cases in which I supposed that the origin was tuberculosis. In a considerable number of these cases the main lesion has been in the drum-head below the extremity of the handle of the malleus. I recall the case of a young man who had trouble at the apex of both lungs when he came under observation. A short time previous he had begun to have slight ringing and a sense of dullness in the ear. This had gone on for two or three days, and then when blowing his nose, he found that he whistled through his ear. In the ear complained of I found an opening looking as though it had been removed by a punch. The opening was elliptical. Within a few days the same thing occurred in the other ear.

DR. J. A. ANDREWS, of New York: In regard to the presence of the bacillus in middle ear trouble occurring with phthisis, although I have examined a large number of cases, I have never found the bacillus.

DR. BUCK: I have not looked for the bacilli; but even if they are not found, tuberculosis should not be excluded.

DR. J. ORNE GREEN, of Boston: I have been much interested in this paper. When I find this destruction coming on without pain and without discharge, I at once suspect a tubercular diathesis, and I generally find a history of it. I also agree with the speaker that only the very mildest measures can be used. Strong applications make the trouble worse. Twice in cases of advanced tuberculosis I have seen on examining this membrane, little white glistening points about the size of a pin-head, not secreting at all and in one case with no congestion. In both cases the spots disappeared in a few days, and within twenty-four hours there was a little clean punched out opening in the drum membrane. This occurred without any discharge. It seemed to me that I was dealing with isolated tubercles in the tissue of the drum membrane. One of these cases died a few months later from the general disease.

DR. A. H. BUCK also read a paper on
CERTAIN TECHNICAL DETAILS RELATING TO OPERA-
TIONS ON THE MASTOID PROCESS.

The speaker first referred to the objections which had been made to the drill. It has been stated that there is danger of plunging the drill into the lateral sinus or even into the brain. He had, however, found no tendency for the drill to go astray. It had been said that the opening made was too small, but any sized drill might be made. He used a drill one-fourth of an inch in diameter until the antrum was reached, and finished the operation with a smaller drill. This gives a sufficient opening for drainage. Where there is a large sequestrum, it is necessary to make a larger opening. The objections to the use of the chisel were next taken up. When this is used the wound in the adjacent soft parts must be larger, and the opening in the bone is more extensive, leading to a depressed cicatrix. More time is required in the operation and it is not free from danger. A study of the statistics of both methods seems to show that there is nothing to warrant the statement that chisels and gouges are to be greatly preferred to drills in establishing opening into the mastoid process.

In operating with the drill, after making an opening, he cuts out a little canal for the escape of the discharges, for the opening made by the drill is covered by the flap when it comes into position. For the first four or five days after the operation, the wound is irrigated once a day with a bichloride solution, 1-2000.

Dr. Buck said that in his earlier operations, he applied the drill a short distance in front of the vertical line. His present plan is different. A straight vertical incision three inches long is made. By this means he exposed the mastoid process where it curves into the meatus. The drill is then applied to the first flat surface. The only difficulty is in establishing the final communication between the canal and the antrum.

DR. J. ORNE GREEN: I have used the drill almost entirely. I prefer to make a small opening at first, and I am then guided by what I find. Some cases require a large opening, and in such cases, the gouge and chisel will come into play. In the majority of cases, a small opening is sufficient. In some of these cases the use of the dental engine is very applicable. I have a modification of the engine which may be screwed to a table. It is turned by a handle and any one can furnish the power. No skill is required, as in the engine worked with the treadle. Used in this way, I have found the engine of great service. In the cases which I have operated on, I have put in a drainage-tube and kept it in as long as possible. In the after-treatment I have used a solution of carbolic acid, 1 to 80. Of late years, I have applied an anti-septic gauze dressing and kept that on.

DR. H. KNAPP, of New York: I wish to make some remarks in favor of the chisel. With the chisel, you can at every step observe the condition of the tissue which you are cutting. With the chisel, you have a perfectly smooth surface, rendering it easier to cleanse the wound. It is also very easy to man-

DR. H. D. NOYES, of New York: There is much less danger in the use of the chisel than of the drill. There are often great differences in the anatomical relations of the parts. The lateral sinus is not always found in the same place. With the chisel or the gouge, you explore the part layer by layer, and ascertain how the parts are situated. This is a strong argument in favor of the instrument.

DR. J. A. ANDREWS: In my operations, I have always used the chisel, but have always begun with the drill. I believe that the chisel is the best instrument and can be used with more caution than the drill. I always make a large opening, for I believe that a collection of pus should always be given free vent.

DR. E. GREUNING: I have opened the mastoid process seventy-seven times. At first I used the drill, and in acute cases the results were all that could be desired. The drill was, however, not applicable to all cases, and I have since used the chisel. A small opening may be made with the chisel. What can be done with the drill can be done with the chisel.

DR. BUCK: From the direction which the discussion has taken it might appear that I am in antagonism with the chisel. I am not in antagonism with the chisel in those cases where a large portion of bone is to be removed. I leave those out of consideration in my paper. Where a large mass is to be removed, it cannot be removed with the drill. The two instruments cannot come into conflict.

A communication with reference to the organization of *A Congress of American Physicians and Surgeons*, was presented and referred to a committee consisting of Dr. C. R. Agnew, Dr. H. Knapp and Dr. John Green to consider and report at the evening session.

EVENING SESSION.

DR. H. KNAPP, of New York, read a report of a
FATAL TERMINATION OF A CASE OF SCLEROSING
MASTOIDITIS AFTER CHISELING OF THE BONE.

A man, aged 50, had extensive suppuration in both ears after scarlet fever in childhood. The right ear became totally deaf, and the left very hard of hearing, became deaf (hearing reduced to a quantitative perception of sound) by a recent attack of dizziness. Dr. Knapp found both tympanic membranes absent, the cavities sclerosed in both, pale in the right but congested in the left ear. Behind the left ear was found a cavity fully an inch deep, lined with immovable skin, the result of former exfoliation of bone. Three weeks later facial paralysis on the left side occurred. It disappeared in two weeks, under steaming and large doses of iodide of potassium. Two weeks later, the patient suffered with constant intense headache and nausea. The mastoid was opened to the depth of half an inch by chiseling. The bone was compact and in the depth, very vascular. During the first two days, the patient was sleepy; could not be aroused on the third and died comatose on the fifth. No autopsy was allowed.

Death was due to traumatic meningitis. In regard to opening the bone in sclerosing mastoiditis, the

prognosis is good when the sclerosis is the result of catarrhal or plastic inflammation, but bad when it was the consequence of old caries or necrosis. There are cases on the border line, and even when the prognosis was bad, the indications might be strong. The operation will rescue a certain number of the otherwise fatal cases.

DR. POMEROV, of New York, reported

A CASE OF ABSCESS OF THE MASTOID CELLS WHERE THE CHIEF INDICATION FOR OPERATION WAS ELEVATION OF TEMPERATURE.

A. S., age 20 years, fairly robust, had a violent attack of otitis of the right ear, which came on Jan. 30, 1886. The following morning, there was free discharge. February 1, he entered the hospital when a large perforation was found; a poultice and warm douches was ordered. By February 4, the membrane looked almost normal. There was some pain in the occiput and a temperature of 103.6. Ten grains of quinine with twenty grains of iodide of potassium to be repeated in three hours was ordered. This was followed by a reduction of two degrees in the temperature. The following day the temperature again went up, and it was apparent that a purulent process was going on. There was no swelling over the mastoid and the pain was no greater than might be expected from a neuralgic condition.

After consultation, it was decided to open the mastoid process. A drill was introduced and from four to six drops of pus evacuated. After the operation the patient continued to improve until he was discharged cured.

DR. J. A. LIPPINCOTT, of Pittsburg: Something over two years ago, I operated in a case of sclerosing mastoiditis which had been suffering intense pain for twelve months, and which did not yield to alterative and tonic treatment. After the operation, the patient remained well for thirteen months. The pain then returned and continued twelve months in spite of all treatment. Last March, a second operation was performed, and a larger opening with the drill made. No benefit was produced.

DR. KNAPP: I should like to state that the cases which I have reported where benefit followed chiseling open a sclerosed mastoid, have remained well.

DR. CHARLES H. BURNETT, of Philadelphia, reported

TWO CASES OF CHRONIC PURULENT INFLAMMATION OF THE ATTIC OF THE TYMPANUM, WITH PERFORATION OF THE MEMBRANA FLACCIDA, TREATED WITH PEROXIDE OF HYDROGEN.

In the first case no application had had the same good effect as the peroxide of hydrogen. Every other medicament had seemed to irritate rather than heal the inflamed mucous membrane. In the second case, the discharge which had been very chronic was promptly checked by the use of the peroxide of hydrogen.

The chemical formula of this drug is H_2O_2 , and by its affinity for albuminous matters, especially those of pus, it seeks every particle of this matter, in a cavity like the middle ear, and thoroughly cleanse the parts. The union with pus is shown by a copious foam, which

boils out of the external ear. When the foaming ceases and the peroxide returns clear, the diseased cavity had been thoroughly cleansed. In many cases this seems sufficient to effect a cure. Where there is a perforation in the membrana flaccida, the application is made by means of the tympanic syringe, the long and slender nozzle of which is introduced through the perforation at the attic of the tympanum. The peroxide is used undiluted.

DR. WILLIAM S. LITTLE, of Philadelphia, read a paper entitled

IN THE PHYSIOLOGY OF HEARING IS THERE AN OVERLAPPING OF EACH AUDITORY FIELD THE SAME AS IN BINOCULAR VISION?

Cases of one-sided deafness afford the opportunity of mapping out the auditory field for one ear, and it is found with the watch at two feet from the ear the tick can be heard about ten or fifteen degrees across the median line of the head. This gives more scope to hear sounds produced on the side of the head opposite the good ear. The tuning fork is not heard even up to the median line on the side of the ear tested. The watch has been used in making the observations. If the field of one ear reaches beyond the median line to about ten degrees, we have when both ears are normal, an over-lapping of each field to the extent of fully ten degrees on either side of the median line in front, above and behind the head. Each ear hears in this area of twenty degrees. Outside of this area, each ear hears singly. By means of this, there is no need to turn each ear towards the source of sounds which reach the individual. The direction of sound is best found in this way for safety in walking and maintaining the erect position. Sudden loss of hearing on one side puts the sufferer to great annoyance, as the ability to determine the direction of sounds is in a measure lost, the patient often looking in the wrong place when called. It is fully as perplexing, if not more so than in a case of sudden loss of sight in one eye, making seeing dependent on one organ of vision. The attempt to restore hearing should be directed not only to obtain hearing in a line directly in front of the ear, but also to increase the area of hearing in the affected ear or in both affected ears, till it reaches if possible, the coalescence seen in normal ears.

The literature of the subject of acoution and otology does not give any information on this point. Too close a comparison between the eye and the ear cannot be made. The auditory and optic nerves respond to very different media. The auditory nerve has no commissure or decussation of fibres like the optic, and has a less central position in the cerebrum.

The proposition with reference to the organization of

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was discussed and a Committee of Conference was appointed, consisting of Drs. C. R. Agnew, New York; H. Knapp, New York; John Green, St. Louis; W. H. Carmalt, New Haven, and George Strawbridge, Philadelphia.

OFFICERS FOR THE ENSUING YEAR:

President, Dr. J. S. Prout, of Brooklyn; Vice-President, Dr. Samuel Sexton, of New York; Secretary and Treasurer, Dr. J. J. B. Vermyne, New Bedford, Mass.; Committee on Membership, Drs. Gorham Bacon, W. S. Little and E. W. Bartlett.

The following were elected to membership: Dr. J. B. Emerson, of New York; Dr. J. O. Tansley, of New York; Dr. J. L. Minor, of New York; Dr. Henry L. Morse, of Boston; Dr. Huntington Richards, of New York, and Dr. T. Y. Sutphen, of Newark, New Jersey.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twelfth Annual Meeting, Held in Quincy, Ill., July 13 and 14.

THE PRESIDENT, ARCH. DIXON, M.D., OF HENDERSON, KY., IN THE CHAIR.

In the absence of the Secretary, Dr. E. B. Montgomery, of Quincy, was made Secretary.

DR. H. M. LANE, of Carthage, Missouri, read a paper on

YELLOW FEVER IN BRAZIL,

giving some of his observations and experiences in the use of Freire's method. He asked that the Society memorialize Congress on the question of appointing a committee to investigate the method of Freire.

DR. LOUIS BAUER, of St. Louis, presented a patient on whom he had operated performing

LAPAROTOMY FOR SYMPTOMS OF ILEUS,

but had discovered an abscess in the liver from which he drew a quart of pus, afterwards washing out the abscess cavity with antiseptic fluids. A portion of the gall-bladder sloughed out, and the large intestine was perforated. The patient made a good recovery.

DR. F. W. BEARD, of Vincennes, Ind., related a case in which he had observed emission of semen in death by hanging.

In the evening DR. A. H. OHMAN-DUMESNIL, of St. Louis, read a paper on

AN UNUSUAL CASE OF LUPUS ERYTHEMATOSUS.

In his case, a farmer 52 years of age, the lupus involved the dorsum of the hand and arm, but occasioned no complaint on the part of the patient. He used a concentrated solution of lactic acid in the treatment of the case. He had several microscopes and illustrated the pathology of the disease.

THE PRESIDENT read a paper on

PERINEAL LACERATIONS,

giving an account of Simon's method of operating.

DR. I. N. LOVE, of St. Louis, read a paper on

ARTIFICIAL ALIMENTATION.

He regarded the skin, the rectum and the vagina as surfaces from which much nourishment might be absorbed and life prolonged. He drew the following conclusions:

1. In cases which demand artificial alimentation, when the conditions will permit, the vagina may be utilized to supplement feeding by the rectum.

2. In some instances diseases of the alimentary canal in its entirety preclude feeding by either the stomach or the rectum, in which cases the vagina may be utilized to practical advantage.

3. That whether the vagina or rectum be used for purposes of feeding, the materials should be as thoroughly digested previous to using as possible; the milk albumen or beef fibre completely peptonized and the starchy matters changed into dextrose or glucose.

4. In many instances the vagina may be utilized for purposes of general medication and stimulation, and the stomach saved for the important one of feeding.

5. In many cases vaginal feeding, stimulation and medication is beneficial; in many others it is a potent means for saving and prolonging life.

6. In both rectal and vaginal feeding the same gentle care is necessary, and one advantage possessed by the latter over the former, is that the vagina is much the more tolerant of intrusion, and can be utilized for an almost unlimited time without revolting.

MORNING SESSION—JULY 14.

A discussion of Dr. Love's paper was had, after which the President announced as a Nominating Committee Dr. Jos. Robbins, of Quincy, Dr. Dudley S. Reynolds, of Louisville, Dr. Frank R. Fry, of St. Louis, and Dr. F. W. Beard, of Vincennes, Ind.

DR. FRANK R. FRY, of St. Louis, presented a paper on some of the current opinions regarding

THE ETIOLOGY OF CHOREA.

He was opposed to the theory of the causal relation between rheumatism and chorea, and believed it to be a pure neurosis.

DR. DUDLEY S. REYNOLDS, of Louisville, offered the following resolution, which was seconded by Dr. Wm. Porter, of St. Louis:

Resolved, That the Mississippi Valley Medical Association adopts as part of its organic law, and binding upon all its members, the Code of Ethics of the American Medical Association. After a spirited discussion the resolution was adopted with only two dissenting voices.

The Committee on Nominations reported the following

OFFICERS FOR THE ENSUING YEAR.

President, Isaac N. Love, St. Louis, Mo.; *First Vice-President*, Joseph Robbins, Quincy, Ill.; *Second Vice-President*, Jacob L. Geiger, St. Joseph, Mo.; *Third Vice-President*, Thos. B. Harvey, Indianapolis, Ind.; *Secretary*, J. L. Gray, Chicago; *Treasurer*, A. H. Ohman-Dumesnil, St. Louis, Mo.; *Assistant Secretary*, Edw. Allcorn, Houstonville, Ky.; *Committee of Arrangements*, Dudley S. Reynolds, Louisville, Ky.; Louis McMurtry, Danville, Ky.; James H. Letcher, Henderson, Ky.; J. N. McCormick, Bowling Green, Ky.; L. B. Todd, Lexington, Ky.;

J. Q. A. Stewart, Frankfort, Ky.; J. M. Holloway, Louisville, Ky.; J. M. Mathews, Louisville, Ky.

The next annual meeting will be held at Crab Orchard Springs, Ky., on the second Tuesday in July, 1887.

The President-elect was escorted to the chair, and after a few remarks appointed the following committee to draft a Constitution and By-Laws: Robert Barclay, of St. Louis, Wm. Porter, of St. Louis, and Jos. Robbins, of Quincy.

Dr. Dudley S. Reynolds read a paper on *Optical Defects in the Eye and their Correction*. Papers were also read by Dr. Amos Sawyer, of Hillsboro, Ill., on *The Therapeutics of Bismuth and Asclepias Tuberosa* (see page 123, JOURNAL of July 31), by Dr. L. H. Cohen, of Quincy, on *Electro-Therapeutics*, and Dr. E. B. Montgomery on the *Therapeutics of Hot Water*.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Preventive Inoculation against Zymotic Diseases—Experiments on Animals in England—Sulphur in Diphtheria—Hospital Accommodation.

At the recent meeting of the Sanitary Institute of Great Britain Dr. T. W. Hime, Medical Officer of Health for Bradford, read a paper on "Pasteur and Preventive Inoculation against Zymotic Diseases." In the course of his address the lecturer dwelt at length upon the discoveries made by Pasteur with regard to rabies. He fancied, he said, that the interest attaching to the disease was to a large extent due to the cruel uncertainty which attended it. If the danger of hydrophobia were reckoned by the number of deaths it would be a comparatively small matter, though in the last thirty-four years there had been 884 deaths in England, and the numbers were increasing. In the ten years ending 1860 there were 98 deaths, and in the next ten years 143, and in the ten years ending 1880, 477 deaths. Nothing, practically speaking, was known of the disease, or of the way in which it was propagated, until Pasteur's time. He undertook his investigations in 1879, and by the next year he had discovered that if one had wanted to produce the disease certainly and without doubt it was necessary to resort to inoculation with nervous tissue. By 1884 Pasteur had inoculated a large number of animals, and he had discovered that if an ape were inoculated with the material taken from the spinal column of an animal that died mad, and the virus was passed on to successive apes, the effects became milder and milder; on the other hand, in guinea pigs it became stronger, and made them perfectly savage. Rabbits also suffered with a greater degree of intensity as the series became longer. In July last the first human patient, a boy, was inoculated by Pasteur, after consultation as to whether the operation was justifiable. Since that 1474 persons had been inoculated, 49 for wolf bites, of whom seven had died, and 1425 for dog bites, of whom four had died. Eliminating the cases still pos-

sibly in danger, he found that there were 113 persons who had been treated after being bitten by animals proved, either by the death of other persons bitten by the same animals, or by experiments, to have been rabid. Of these only one had died. Then 936 persons had been treated for bites from animals proved by chemical observation to have been rabid. Amongst these there had been only three deaths. Another class of cases was that in which persons had been bitten by dogs which had escaped, and were not proved to have been mad. Amongst these there had been one death. Of the persons bitten by wolves the mortality was 14 per cent., whereas, so far as any statistics were available, it was, without Pasteur's treatment, something like 80 per cent. Wolves inflicted very severe wounds, and a large amount of virus was consequently absorbed. The efficacy of Pasteur's treatment for wounds inflicted on the hands or face, the most exposed parts of the body, was shown by the fact that the mortality was only 1.8 per cent, whereas it was known to have been 88 per cent. amongst persons bitten previously to his discoveries. The value of his system in protecting dogs had been proved beyond a doubt by the Commission appointed by the French Government. Out of twenty-three dogs presented by Pasteur after treatment for the experiments, the Commission had not succeeded in making a single one mad; whereas out of nineteen operated upon without previous treatment, fourteen had died mad. No scientific man of standing had made any objection to Pasteur's method, and he (Dr. Hime) hoped that the evidence he had laid before the Institute would be thought conclusive. He added that Pasteur had taken no patent, and had sought neither fortune nor honor at the hands of the French Government. His laboratories were open to all to go and investigate for themselves. In conclusion, he said it was a fortunate thing that M. Pasteur was not an Englishman, for if he had been it would have been impossible for him to embark in this country upon the work which he had so successfully prosecuted for the benefit of mankind. Dr. Hime himself is about to undergo treatment at the hands of M. Pasteur, having recently been severely wounded while conducting a post-mortem examination on the body of a dog that had died of hydrophobia.

The report from inspectors on experiments performed on living animals during the last year has just been published. The total number of experiments performed during the year was about 800. Of these 210 were done under the restrictions of the license alone, and eighty-two lecture demonstrations under similar restrictions. As regards the amount of pain involved in these experiments, in all of them, except those performed under special certificates, the animals are rendered insensible during the whole experiment, and are not permitted to recover consciousness. With regard to the experiments under special certificates, which dispense either partially or entirely with the use of anæsthetics, no less than 328 consisted, so far as any operative proceeding was concerned, in simple inoculation or hypodermic injection, either with some

morbific virus or for the purpose of therapeutic inquiry, and in which the administration of an anæsthetic, to which all animals have a great repugnance, would only entail needless annoyance and distress. Considered from the returns that have been received from various operators, and from other considerations drawn from their reports, it appears that the number of animals that suffered any appreciable pain might be estimated at thirty-five or forty, and these, for the most part, frogs. Although the number of experiments in 1885 was nearly double those performed in 1884, the increased number consisted of experiments not, or scarcely, involving any appreciable increase of suffering of the animals employed.

Arguing from analogy, and seeing the success of sulphur in vineyards for the cure of *oidium*, Dr. Corbin has been trying it as the most rational treatment to adopt to destroy the fungus of diphtheria. Finely powdered sulphur blown down on to the membrane through a quill or glass tube causes no pain, and very little distress to even very young children, and in such cases it is the only local treatment which the Doctor finds himself able to adopt. Carbolic acid spray he has found useless as a germicide, because the mouth and throat will not tolerate it of sufficient strength to destroy the vitality of the false membrane, but in strength of 1 in 66 or 1 in 80 it is very soothing to the inflamed throat. Boracic acid spray, on the contrary, he finds extremely useful, for it appears to have the power of dissolving the membrane whose vitality the sulphur has destroyed, and thus a fresh surface is exposed for the next application of sulphur to act upon.

The following figures are interesting: In Glasgow there is hospital accommodation for one in 700 of the inhabitants; in Manchester one in 500; in Dublin one in 200; while in North London there is only one hospital bed for every 25,000 of the inhabitants.

DOMESTIC CORRESPONDENCE

THE ASSOCIATION OF AMERICAN PHYSICIANS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Referring to the communications in your issues of the 24th and 3d ults, with regard to "The Association of American Physicians," it was with extreme reluctance, and only after recalling the fact that published matter of this kind becomes the source of history—history which in this instance would be erroneous—that I decided to write briefly the actual history of the formation of the society.

First, the organization was altogether independent of and prior to the idea of a Congress of American Physicians and Surgeons. The original suggestion came more than three years ago, *not* from Philadelphia or New York or Boston, but from Toronto, Canada. It was based upon the feeling that such a society had become almost necessary in view of the fact that all departments of medicine except general medicine and pathology were represented in special societies devoted to their interests. Further, it was

long after the arrangements for organization were essentially completed, that the idea of a Congress of American Physicians and Surgeons was formulated by the American Surgical Association.

Second, the Association was not formed in antagonism to the American Medical Association, and it was a matter of serious solicitude with some of the founders lest such interpretation should be put upon its formation; but this was not considered sufficient reason for giving up a plan which promised so much for medicine and pathology. So far as I know, no member who is also a member of the American Medical Association has "forsworn his allegiance" to the latter, as is alleged by your Philadelphia correspondent.

Third, in selecting original members for the "active list," it was desired to secure men who had been and still are active in furthering the interests of medicine and pathology either as practitioners, teachers or writers. That this was accomplished with reasonable success, when it is remembered that a certain number of vacancies are maintained for the present, will, I think, be conceded by the unprejudiced observer.

Finally, with regard to the name chosen, a moment's consideration should satisfy the critic that the use of any other "article" than the "definite" would produce a ludicrous and impossible title. Such a title would be "*An* Association of American Physicians," "*An* American Gynecological Society," "*An* American Ophthalmological Society," etc.

I should have been glad to give your Philadelphia correspondent or any one else any information desired, had it been sought. Respectfully,

JAMES TYSON,

Secretary of the meeting at Washington, 1886.

PROPOSED NEW MEDICAL ASSOCIATION.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—While not one of the Original Committee of Seven, I nevertheless thought I was in close affiliation with them; but alack-a-day! I find that I am farther off than a poor relation. Where I am now I can hardly tell. I am not in holy fellowship with the American Medical Association, nor have I been included in the one hundred eminent martyrs; alas! not only not included, but not even invited to include myself. My pride has had a great fall, but by my conscience I don't deserve it, for I fought and bled as much as any of the limited one hundred, and more than a great many.

You may say that I am not eminent. Well, I will acknowledge that I once thought so myself, but the *Medical Record* has maintained that all who asserted their independence, manhood, etc., and who acted in sympathy with the nonconformists, became *instant* eminent. I fulfilled all these conditions; ergo, I am eminent.

I was formerly under the impression that only new-coders were eminent practitioners, until the Editor of the *Medical Record* (who is authority on such subjects) enlarged the definition so that even old-coders might become eminent. As I have said,

I have complied with the requisite stipulations for old-coders to attain the modern but select degree, and yet I am left out in the cold. I suppose there must be a still higher degree, to which I have not yet attained, which places me among the great majority of the discarded.

However, I will not be so slighted, but propose to organize "The Association of Eminent American Physicians of the Second Degree"—limited; place of meeting Washington, D. C. You need not think we are not going to have our little whack at the Ninth International Medical Congress—so beware!

"IMPRIMATUR."

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

FAVUS OF FOWLS AND MAN.—At a recent meeting of the Paris Biological Society, M. NEUMANN stated that the favus of fowls is identical with the favus of human beings. He inoculated a young dog with fowl favus and another with the favus of the human subject; the affections of the two animals presented the same clinical features. Both were quickly cured without treatment as generally happens in this affection with animals. The same experiment was repeated on two rabbits with the same results. These researches of M. Neumann are fresh facts added to those already accumulated, showing the necessity for sanitary inspection of farmyards.—*Sanitary Record*, July, 15, 1886.

THE OUTLOOK FOR THE CONGRESS.—PROF. W. F. PECK, of the Iowa State Medical University, who is now making an extended tour of Europe, writes as follows from Amsterdam:

"I visited Prof. Esmarch the other day in Kiel. He will come to the International Medical Congress. From what I can learn the profession of Europe will send a large delegation. Prof. Billroth told me that he expected to attend, and Carl Braun will accompany him."

DISINFECTION OF RAILWAY CATTLE-TRUCKS.—DR. REDARD, Surgeon-in-Chief to the French Railways

has lately presented a detailed report on the disinfection of cattle-trucks to the Government department charged with the railway administration throughout France. After reviewing the cleansing methods adopted in different countries, and recording experiments with chemical antiseptics and disinfectants, Dr. Redard arrives at the following conclusions: Chemical disinfectants are bad microbicides, requiring large quantities and prolonged contact. Spores and germ-corpuscles resist almost all chemical disinfectants. Some substances, which are very active against spores and bacteria, are very frequently powerless against a virus, unless incorporated with it freely and long. Heat is the disinfectant *par excellence*. Numerous experiments with virus and successive inoculations proved that absolute disinfection can only be obtained with certainty with steam superheated to $+110^{\circ}$ C. This is not easy to obtain. The different processes hitherto in use only yield boiling water or steam below 100° C. Dr. Redard therefore proposes to pass the steam through a serpentine coil placed in the locomotive boiler. Steam from 110° to 130° C. may thus be obtained.—*Lancet*, July 10, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 24, 1886, TO JULY 30, 1886.

Col. Joseph B. B. Brown, Surgeon, retired from active service, July 26, 1886. (S. O. 171, A. G. O., July 26, 1886.)

Major J. R. Gibson, Surgeon, ordered from Dept. East to Dept. Mo. on expiration of leave of absence granted in S. O. 158, c. s., A. G. O. (S. O. 168, A. G. O., July 22, 1886.)

Major Edwin Bentley, Surgeon, ordered for duty as Post Surgeon, Ft. Davis, Tex. (S. O. 92, Dept. Texas, July 22, 1886.)

Major M. K. Taylor, Surgeon, granted leave of absence for one month, with permission to apply for one month's extension. (S. O. 77, Dept. Mo., July 24, 1886.)

Major Passmore Middleton, Surgeon, ordered to Dept. East from Dept. Mo. (S. O. 168, A. G. O., July 22, 1886.)

Capt. Joseph B. Girard, Asst. Surgeon, granted leave of absence for three months, with permission to go beyond sea. (S. O. 170, A. G. O., July 24, 1886.)

Capt. Samuel O. Robinson, Asst. Surgeon, ordered for duty as Post Surgeon, Ft. Brown, Texas. (S. O. 92, Dept. Tex., July 22, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JULY 31, 1886.

Lumsden, J. A., P. A. Surgeon, to duty at Marine Barracks, Washington, for month of August.

Cordeiro, F. J. B., Asst. Surgeon, ordered to receiving ship "Minnesota"

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED JULY 31, 1886.

Long, W. H., Surgeon, granted leave of absence for fifteen days. July 30, 1886.

Sawtelle, H. W., Surgeon, to proceed to Portland, Oregon, and Port Townsend, W. T., as inspector. July 29, 1886.

Devan, S. C., P. A. Surgeon, granted leave of absence for ten days. July 26, 1886.

Fattic, J. B., Asst. Surgeon, granted leave of absence for twenty-nine days. July 26, 1886.

Carmichael, D. A., P. A. Surgeon, granted leave of absence for thirty days. July 24, 1886.

Magruder, P. M., Asst. Surgeon, to proceed to Cairo, Ill., for temporary duty. July 22, 1886.

ORIGINAL ARTICLES.

THE PROGRESS OF PNEUMATIC DIFFERENTIATION.¹

BY HERBERT F. WILLIAMS, M.D.,
OF NEW YORK.

In the *Medical Record* of January 17, 1885, is found the first report of the application of the Pneumatic Cabinet to diseased conditions of the lungs. This process was called Pneumatic Differentiation and the description was entirely confined to what in the perfected instrument shown to day is the first act, *i. e.*, producing rarefaction in the cabinet about the patient and compelling him to respire the normal atmosphere. That report contains the history of sixty-two cases treated in this manner, seven of which were given in detail, and five there classed as recovered further appear in my second paper delivered before the American Climatological Association, and published in the *New York Medical Journal*, October 3, 1885. Further reference to these cases will be made in a clinical report which I shall have the honor to present to the same Association during the present month. It will show these cases remaining in good health up to January of this year, a space of nearly two years in each case, and without further treatment.

Dr. Houghton, of Chicago, published a report entitled "Pneumatic Therapeutics" in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, November 7, 1885. He advanced some new and ingenious theories suggested by the cabinet in relation to the causes of peri- and inter-vesicular deposit, and reports thirty-four cases of various pulmonary affections, twenty-five of which were classed as phthisis in different stages, four of which in the acute stage recovered and ten improved; three did not improve. Dr. Jensen, the same JOURNAL and date, confirms one of these cases as acute catarrhal phthisis recovered.

Dr. E. Tiegel, of New York, in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, in the issue of November, 28, 1885, discussed "The Physiological Action of the Differential Pneumatic Process on the Circulation." His investigations being made before the present form of cabinet was perfected, he necessarily confined his experiments and arguments to the simple act of immersing the patient in rarefied air while breathing the normal air.

The first full description of the cabinet as perfected was given before the Section on Practice of the New

York Academy of Medicine, December 15, 1885, by its inventor, Mr. Joseph Ketchum, in a paper entitled "The Physics of Pneumatic Differentiation" published in the *Medical Record*, January 9, 1886. This was accompanied by a paper from Dr. E. Darwin Hudson, Jr., in the same issue entitled "Present Status of the Pneumatic Treatment of Respiratory Diseases," in which he refers to the preceding work in this field, and shows the value and individuality of the cabinet.

In the *Boston Medical and Surgical Journal*, of July 16, 1885, appears an article from Dr. V. Y. Bowdich, of Boston, entitled "The Treatment of Pulmonary Diseases by means of Pneumatic Differentiation."

Dr. F. Donaldson, Jr., of Baltimore, in the *Maryland Medical Journal*, of February 13, 1886, publishes an article entitled "The Pneumatic Cabinet and Pneumatic Differentiation," in which in a postscript he speaks of the cabinet as giving excellent results, and briefly reports two cases. Among other professional publications on the subject, are those of Dr. W. Everett Smith in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, November 14, 1885, and the *Medical and Surgical Reporter*, of Boston, February 20, 1886, and Dr. Houghton in *St. Louis Weekly Medical Review*, January 2, 1886. Dr. Sidney A. Fox, of Brooklyn, read a paper before the Kings County Medical Society, February 16, 1886, in which he reported sixty-eight cases of pulmonary diseases treated by pneumatic differentiation. Many other papers have been read before County and State Societies, and are now awaiting publication in the official journals.

In consultation and correspondence with a large number of physicians, I have found that nearly all have been looking for a method whereby we might topically medicate the lungs. In this process that result has been accomplished. Mr. Ketchum has shown that we can not only carry a medicinal agent into the remotest alveolus, but condense it there.¹ It now remains for patient, accurate and careful inquiry to decide whether such medication is efficacious and expedient. Have we not here a field of immense breadth, and will it be fair to adopt the pessimistic argument that nature seeks by the expanse of turbinated bone, and the protected glottis to warm and purify the air before it meets the delicate membrane where its physiological purpose is subserved.

To offset the argument that to change the humidity or temperature of the air, or to burden it with foreign

¹ Read in the Section on Practical Medicine at the Thirty-Seventh Annual Meeting of the American Medical Association.

matter would seem illogical and impracticable, we have, first, the result of clinical evidence; second, analogy. Our practical experience teaches us that the pulmonary mucous membrane and deeper tissues tolerate invasion without serious disturbance. We know how readily water is absorbed by the lungs in conditions of partial drowning. Effused blood with its various inflammatory products, may not itself occasion disturbance by its physical presence in the deeper pulmonary tissues excepting so far as it excludes air. Nothing that prudence could suggest as a remedial agent could be any more irritating than the decomposed and ichorous discharges that sometimes bathe the inter-pulmonary surfaces. Analogy shows that surgeons have for years been disregarding the physiological function of a part when disease demands interference. The serous membranes and cavities have been invaded and washed with the most irritating agents. Every mucous tract of the body has demonstrated its tolerance of violence. But it may be asked what is the effect where an agent applicable to a diseased pulmonary area is inevitably introduced into areas remaining in health? There is nothing in this question that exclusively applies to this process. Would not many of our surgical operations give doubtful evidence of our mechanical skill if kind nature did not endure, forgive and repair? When the head throbs with fever that is threatening life, do we hesitate to give an agent of the power of quinine in antipyretic doses? For a remote ache or pain is it not sometimes necessary to narcotize the entire nervous system?

Since the days of Sir James Y. Simpson, McDowell and Morton, have we not chilled the inter-pulmonary tissues with chloroform and ether, and though as I believe by so doing we invite congestion, does it deter us when the greater necessity arises?

Again, is there anything ethereal about the pulmonary tissues that prohibits an effort to cleanse and disinfect? Indeed, in some cases it seems as though the process of repair in pulmonary tissue is as rapid as in the scalp or tongue, and perhaps for the same reason. There is a great diversity, or I may better say, confusion in the professional mind as to whether Koch's bacillus is the cause or concomitant of tubercular disease. Certain it is that a few well-known agents are capable of destroying these organisms. It is moreover certain that in every case of phthisis in which they are found serious, progress has been made or violent symptoms continually threaten.

There must have been a time in the history of a given case, when lung tissue rendered congenial for the lodgment of its bacterian enemy received its first impregnation. Could we ascertain this period. Can we imagine any surer method of extermination than to introduce at the seat of lodgment a well-chosen germicide. Would we care then if the adjacent tissues were sterilized? Indeed, I think I have already demonstrated,¹ that by the differential pneumatic process it is possible to save healthy lung tissue from tubercular infiltration.

It is then desirable to have in our power a means

by which we can medicate the lungs, and with the conviction in my mind that amounts to a certainty, I neither shrink from the possibilities of therapeutic error nor grow discouraged, because in a given case the relation between the extent of disease and a well directed remedy is insurmountable. I have certainly more than once secured results which could only be fully explained consistently with the hypothesis that a thorough and prolonged course of antiseptics had by coincidence, rather than calculation, been instituted at the time when tubercular germ life though present, had not established an impregnable foothold. When from the contemplation of this hypothesis I turn to the constant progress of scientific inquiry, and especially the recent developments on biological analysis, I desire to record the prediction that at no distant day a system will be developed and adopted, whereby we can certainly sterilize a pulmonary area, and gain the mastery of tubercular disease to a degree hitherto thought chimerical. However remote the hope thus expressed, it surely affords encouragement to those advanced investigators who systematically employ the microscope as an aid to diagnosis. This method will also detect the early manifestations of grave diseases and will fortify our diagnosis against heretofore unanswerable accusations of unwarrantable conclusions.

The pneumatic cabinet as a mechanical device, independent of its ability to convey a remedial agent to diseased pulmonary structure, and condense it there, is itself a factor of no small moment as a salutary measure. Its capacity to increase expansion, to thoroughly ærate the blood, and to thereby promote assimilation and functional activity is attested by the uniform experience of those who have observed its effect.

In patients where the correction of faulty frame developments or distortion is retarding health, this may alone confer all the benefit required. In certain conditions of instituted disease, such correction may render cure or improvement possible to the exclusion of remedial influences.

These results, certainly the most obvious, appeal to some investigators as the most important of its accomplishments.

If in the selection of appropriate agents, whether emollient, sedative, germicidal or stimulating, there is a field for discrimination, equal opportunity is offered for choosing, first, the character of force, and secondly, the degree. The annals of medicine are replete with the history of cases treated by means of air chambers, where air at different degrees of density and humidity exerts a therapeutic influence. Drs. Bowditch and Hudson have well shown the essential distinction between this and all other devices for treating pulmonary disease.¹ Waldenberg's gasometer seems to some to produce essentially the same mechanical effect.

In pointing out the fallacy of such a conclusion I do not mean to imply the inutility of inhaling condensed air or of expiring into rarefied air. For these purposes the Waldenberg condenser is complete and

¹ N. Y. Medical Journal, October 3, 1885.

¹ Boston Med. and Surg. Jour., July 16, 1886. (Medical Record, Jan. 9, 1886.)

sufficient, for in order to duplicate this by the pneumatic differentiator, it would be necessary to have the patient to stand or sit outside the cabinet and breathe into it either at pressure or vacuum. The processes then would be nearly identical.

But as to the operation of the pneumatic cabinet, what are the facts? In the first act, that of immersing the patient in rarefied air, say at two inches fall of the manometer, we remove one-fifteenth of the atmospheric pressure, which is taking away one pound pressure per square inch of the superficial area of the lungs. If, as frequently happens in the progress of phthisis, communicating and healthy bronchi have become occluded by sputum, the imprisoned air must expand, and a corresponding force be brought to bear behind the occluded point. This I have demonstrated before you to-day.

The rarefaction then is allowed to run down to one inch of the manometer or to a safe and prudent degree. Now begins the act of inspiring the normal atmosphere, while immersed in vacuum, which to some seems equivalent to inspiring the condensed air of Waldenberg, but there is not a similarity excepting that of the force of the weight of the normal atmosphere. The patient's thorax relieved of a part of its burden, the inter-pulmonary molecules of air separated from each other are inviting their fellows from outside, and are ready to assume normal relations when they meet. In other words an aspirating force is created, that compels a circulation of air with its normal quota of oxygen which no prudent amount of direct force could produce in the alveolus. This may be amplified as follows: In the cabinet the atmospheric support of the chest walls being withdrawn, each ultimate cell is expanded, and there the initial energy is developed. This expansion is communicated along the respiratory avenues to the respiring air. Thus each molecule separated from its neighbor by the increased space of its habitation permits the tidal air at normal density to penetrate into the enlarged cell.

While in the compressed air method the initial energy is developed in the apparatus and the tidal air is forced down and super-imposed on the cushion of residual air. The inefficiency of compressed air to carry moisture marks a further and important difference.

Second.—Compressing the air about a patient in the cabinet, and allowing him to expire into the normal atmosphere. Here again carelessness may not detect the difference between this and expiring into rarefied air. At a pressure of two inches of the manometer we are exerting a collapsing force about the lungs of one pound per square inch. The patient now makes an expiratory effort into normal air. Should it be thought desirable the pressure can be carried to such a degree that volition cannot prevent the imprisoned air from rushing out through the alveoli, bronchi and trachea, and unlike the act which it is thought to simulate the initial movement is in the alveolus, for its air is driven and not sucked out.

The third act, *viz.*, that of alternating compression and rarefaction is unique, comprehensive and unapproached by any previous device. Mere respiration

can be maintained if necessary independently of volition. Moderately applied, it affords a respiratory assistance, which many diseased conditions welcome. It further promotes the condensation of vapor, by increasing the relative difference of atmospheric pressure at inspiration and expiration.

This description must suggest to your minds many conditions in which if properly applied the process will be of no uncertain value. Time will not permit me to here record the results attained since my last clinical report. The results of independent investigators in different sections of the country, all substantiate the claims originally published. These physicians are located in many of the larger cities, and several are in sections of the country where climatic influence may demonstrate the cause of failure in certain conditions where climatic advantage has been denied. The reports of recovery and improvement are largely in excess of negative results and failures.

As an office instrument at present applied the cabinet fully answers the purposes for early conditions or for the occasional relief which irrecoverable cases can obtain. For methods of diagnosis one application will frequently so change the physical character of the chest sounds that that which before treatment was obscure and indefinite can readily be appreciated and classified. Every one must see that in occasional cases the cabinet as at present applied is at an immense disadvantage. This suggests the necessity for the establishment of properly constructed sanitarium where inclement weather cannot interrupt the treatment nor prevent its frequent and, if necessary, prolonged application. In many a case ultimate phthisis primarily induced by delayed resolution of acute disease, be it pneumonia, pleurisy, the essential fevers or the various forms of septicaemia, would have been cheated of its victim if it had been possible to apply this process in the sufferer's sick chamber.

How many times are we called to watch the battle between disease and repair with our hands tied until the moment when Nature's pure air can be made to freely circulate throughout the lungs for the double purpose of preserving their integrity and ventilating the sluggish blood which has so long been poisoning the nervous centers! The utility of the instrument will be greatly augmented when we can have it placed in the sick chamber of such a case. Several prominent practitioners who cannot afford the time to properly administer this treatment have adopted the practical plan of sending their patients to some younger physician in whom they have confidence and with whom they have made agreeable conditions.

The older practitioner having the larger opportunity for detecting the earliest manifestations of disease thus insures his patient prompt institution of an efficient and radical treatment at a stage when recovery may be anticipated.

I have been specially devoted to the study and analysis of the pneumatic process for the last three years. My experience, now matured, convinces me not only of its far reaching power within the thera-

peutic regions so far developed, but of its promise in fields as yet only suggested. Its use has provoked in many minds rational theories which, as I believe, will employ a generation.

The great mechanical power of the apparatus is apparent to any observer. In ignorant or careless hands it is capable of deadly force. The corollary of power is peril. But perhaps the greater danger is that it may fall into the hands of routinists, who disregarding the necessity of accurate diagnosis may apply it where its use is contraindicated and for the resultant failure condemn it generally.

When it has produced in a given case what may be called the maximum of improvement, whether this is reached by one or one hundred applications, its use should be suspended. An elastic conscience might distort sound judgment so long as the hopeful sufferer proved a source of revenue.

It needs no reflection or argument to suggest the grievous misfortune to humanity if the men who already prey upon the credulous consumptive with no weapons save natural depravity and cunning shall find in the cabinet a device by which they can impress the imagination and perhaps chance upon an exceptional result. Its potentialities of good and evil alike dedicate this instrument to the profession. It should be our desire and, if opportunity offers, our duty to secure it against the temerity of charlatans or abuse by the avaricious practitioner.

It was with a thorough appreciation of these considerations that the inventor sought the counsel of the late Professor Samuel G. Armor who had watched with much enthusiasm the progress of his early experiments. In accordance with his advice, which was later on thoroughly endorsed by Prof. Henry I. Bowditch, of Boston, and other leaders in the profession, an advisory Board of Physicians has been invested with the absolute power of rejecting or accepting any application for the use of these cabinets. This plan has so far restricted the process to absolutely appropriate and trustworthy hands. For the last year of his life, Prof. Armor was chairman of this Board and since his decease Prof. Alfred L. Loomis, of New York, has occupied that position. It is designed to add to this Board a representative physician from each of the prominent medical centers of the country whose more accurate knowledge of the physicians residing in his own community will enable him with greater certainty to accept responsibility for them when entrusted with the apparatus.

This cabinet has already increased the sphere of professional activity and benefit, while it beckons us to further accomplishments. Surrounded by safeguards which preserve it as a strictly professional instrument, it deserves from us to whom it has been thus entrusted, not only faithful test but unprejudiced recognition of its capacities when established by sound reason and clinical evidence.

At my request reports have been sent me by many of those physicians who are using the cabinet, with expressions of opinion and clinical reports. Having occupied already so much of your time I shall only refer to them generally. Others are preparing reports for their State and county society meetings,

and a mass of clinical evidence is being collected which cannot fail to direct attention to this department of pneumotherapy.

Dr. C. B. Herrick, of Troy, N. Y., reports three cases, one of improvement with a gain of twelve pounds, another with a gain of five pounds, and the third a marked improvement from unresolved pneumonia. Dr. W. A. De Watteville, of New York, reports three cases with his conclusions; two of them, both 3d stage cases, became quiescent, the third was a failure.

Drs. Classon and Clarke, of Albany, New York, send full details of one case in which they confidently expect recovery from acute phthisis, with reference to several others in which the process is giving relief.

Dr. R. H. Babcock, of Chicago, reports two cases in which improvement is noticed and says, "It is in my opinion a valuable adjunct." "Its influence over cough and expectoration is of such marked benefit as to alone recommend the method," and speaking of the stimulated circulation says, "were this alone and nothing more the result of treatment with the pneumatic cabinet, this were enough to recommend it to the profession."

Dr. W. Everett Smith, of Boston, reports a case of incipient consolidation at apices in which he does not hesitate to claim a recovery.

Drs. Cutts and Fernald, of Washington, report a case of marked improvement after thirty sittings with a gain of eight pounds in weight and absence of signs of the previous pulmonary lesion.

Dr. E. E. Trudeau, of the Cottage Sanitarium at Saranac Lake, New York, says: So far as he has gone he can bear testimony to the usefulness of the method in those cases where good might be expected from expansion and improved pulmonary nutrition, but in cases where localized antiseptic treatment is indicated it is less satisfactory. He finds its most brilliant field in cases when contraction of connective tissue as in chronic phthisis exists, with mal-nutrition, debility and dyspnoea, also in apical lesion with co-incident constitutional disturbance. He also says: "Most patients suffering from incipient or chronic phthisis have shown more or less marked improvement, one case gaining seventeen pounds in weight with an entire disappearance of all moist sounds in the lungs."

Dr. J. H. Blanks, of Meridian, Miss., has sent me a classification of twenty-seven cases, twelve of which were bronchitis, and in which nine recovered, two improved and one did not improve. Two were unresolved pneumonia, with one recovery and one improvement, and thirteen were of phthisis with one recovery, five improvements, four non-improvements and four deaths. The latter were so far advanced that they were unable to walk without assistance, and one received only four treatments. He also sends full details of two cases, one of practical recovery and one of marked improvement.

252 Madison Av., N. Y.

THE DIFFERENTIAL DIAGNOSIS OF SCROTAL TUMORS.¹

BY D. A. K. STEELE, M.D.,

PROFESSOR OF ORTHOPÆDIC SURGERY IN THE COLLEGE OF PHYSICIANS
AND SURGEONS OF CHICAGO; SURGEON TO COOK COUNTY
HOSPITAL, ETC.

The differential diagnosis of scrotal tumors is not always an easy matter. The peculiar anatomical conformation of the parts, the varied morbid alterations of structures normally located, and the frequent intrusion within the scrotal pouch of dislocated or adventitious tissue renders a positive diagnosis difficult, if not indeed impossible in certain cases. It has been our fortune to witness a number of grave errors of judgment as to the nature of tumors within the scrotum, and our misfortune to occasionally participate in these mistakes. When we consider that a scrotal tumor may be a hernia, hydrocele, orchitis, epididymitis, varicocele, cancer, sarcoma, hæmatocele, or a complication of two or more of these affections, the reason for an occasional blunder is more apparent—and an allusion to previous mistakes may be a reminder of certain diagnostic points that will serve to warn the members of this Society from pitfalls where others have stumbled.

"A tumor is a morbid swelling, prominence or growth on any part of the body." Surround this definition with the scrotal walls and you embrace our subject. The scrotum is a pouch formed of the common integuments for the reception of the testicles. It is evenly divided externally into two halves by a prominent ridge, a continuation of the raphé from the under part of the penis to the perineum. The skin of the scrotum is thin like that of the eyelids, and darker in color than most other parts. It is very loose and extensible, as evidenced in connection with scrotal hernia or very large hydroceles.

The *dartos* is a thin layer of contractile tissue of a reddish-grey color immediately beneath the skin, and intimately connected with its inner surface. Bowman considers the *dartos* to be muscular and composed of "unstriped elementary fibres." Scrotal movements by the *dartos* are involuntary and peristaltic or vermicular in character. Contraction is excited by cold, fright or venereal orgasm; relaxation by heat, old age, debility. Galvanism produces no effect. Beneath the *dartos* there is a quantity of loose cellular tissue. Underlying this we find the superficial spermatic fascia continuous with that covering the lower part of the abdominal walls, and descending to form a sheath for the spermatic cord and enveloping the testis.

Beneath this is the cremaster muscle, which is interesting from a diagnostic point of view on account of its action in elevating the testicles to the abdominal rings, and the fact that sometimes this power of retraction is entirely volitional and might be used by a malingerer to simulate an inguinal hernia. Pre-supposing a thorough knowledge of the anatomy of the testis on the part of my auditors, a detailed description is not needed; it will only be necessary for us to remember the relation of the parts composing these glands. First, the tunica vaginalis,

a delicate serous membrane in the form of a shut sac, enveloping by means of its outer layer all of the testis except its posterior edge and lower extremity, is derived from the peritoneum. The line of attachment is about five lines from the inferior extremity of the testis. Second, the tunica albuginea, a dense fibrous layer forming the covering proper of the gland, but not including the epididymis. Third, the gland structure proper, consisting of the seminiferous tubes, blood-vessels, lymphatics and nerves. Fourth, The epididymis is a continuation of the gland proper, containing the excretory ducts which empty into the vas deferens, which is the real excretory duct of the testicle.

At an early period of foetal life the testes lie behind the peritoneum in the region of the kidneys, being loosely attached to the peritoneum by the mesorchium. The inguinal canal has already been formed, and is occupied by a cord-like structure, the *gubernaculum testis*, which extends from the bottom of the scrotum to the testis, to the under surface of which it is attached, and as the testicle gradually descends during the last months of foetal life the gubernaculum testis shortens and guides the way. At the same time the peritoneum enters the inguinal canal in advance of the testicle, descending in a loose fold as the gubernaculum contracts and draws the testicle down after it. The descent of the testicle is usually completed shortly before the birth of the foetus; and, as a rule, the neck of the peritoneal sac is obliterated by occlusion before the child is born, thus cutting off all communication between the tunica vaginalis and the peritoneal cavity. This occlusion may be incomplete, thus giving rise to congenital hydrocele, or it may occur at two or three different points, leaving free serous spaces intervening, occasioning encysted hydrocele—or hydrocele of the cord. So much, then, for an outline of the anatomical points of our subject.

For diagnostic or clinical purposes tumors of the scrotum may be divided into two general classes, viz.: reducible and irreducible—reducible tumors including all herniæ (except strangulated), varicocele, and congenital hydroceles. Irreducible tumors of the scrotum would include all tumors connected with the testicle, all hydroceles (except congenital), and strangulated hernia. Tumors of the tegumentary surface of the scrotum, such as inflammatory oedema, elephantiasis and epithelioma, are usually so characteristic in their history as to offer no special impediments to a correct diagnosis.

Scrotal hernia may be mistaken for:

1. Hydrocele of tunica vaginalis, cord, or encysted hydrocele.
2. Sarcocoele of the testicle, simple, tuberculous, cystic or malignant.
3. Varicocele.
4. Hæmatocele.
5. Bubo.
6. Undescended testis.

In scrotal hernia, as a rule, the tumor is soft and doughy to the touch, light weight, smooth and regular, painless unless inflamed or strangulated, of sudden advent from above downwards, resonant on percussion, fills the inguinal canal, has cough impulse,

¹ Read before the Chicago Medical Society, July 19, 1886.

gurgles, is of normal color, opaque, may exist on either side, the spermatic cord is concealed, does not fluctuate, aspiration is negative, bowels may be embarrassed. It can be reduced unless the hernia is strangulated or incarcerated.

1. (a) In hydrocele of the testicle the tumor is ovoid or pyriform, develops slowly from below upwards, is firm, tense and elastic, fluctuates, is translucent, dull on percussion; is irreducible; spermatic cord is neither concealed or displaced; the inguinal canal is empty; bowels unaffected; aspiration reveals fluid.

(b) In hydrocele of the cord the difference is that the tumor is circumscribed, encysted, and sometimes reducible, situated usually near the epididymis, but returns after reduction irrespective of position.

(c) In congenital hydrocele the fluid disappears completely within the peritoneal cavity by compression of the tumor for a short time.

2. (a) In sarcocele of the testicle the tumor is usually hard and resistant, heavy, often nodular and irregular; painful; grows slowly; dull or flat on percussion. The inguinal canal is empty; no impulse on coughing; bowels unaffected; irreducible; no auscultatory sounds. Simple sarcocele is chronic orchitis. Both the epididymis and body of the gland are affected. The cord is usually thickened. Abscess of the organ may occur. It is caused usually by an injury followed by inflammatory deposits.

(b) Tubercular sarcocele is met with most frequently in early manhood, and may occur in any constitution; in the strong and robust as well as the weak and cachectic; and although often associated with tubercularization of other organs, it is common enough to find the tuberculous nidus in the epididymis, not as a sequence of gonorrhœal inflammation or some slight injury followed by inflammatory infiltration—as was formerly believed—but as a co-incident.¹ The progress is slow and insidious. The gland at first moderately enlarges with little or no pain, the hypertrophy being especially marked in the globus major. Presently the outline of the tumor becomes craggy or nodulated, and circles around the testicle from behind forwards in the form of a crescent. After several months, this adventitious tissue exceeds in size the testicle proper, and then it begins to soften at points and one or more abscesses burst and discharge a thin shreddy pus. The vas deferens is greatly enlarged.

(c) In syphilitic sarcocele or gummata the history of the patient guides us in the diagnosis. Also, we find that the body of the gland is usually the seat of the infiltration which takes place in the connective tissue between the tubuli seminiferi, the epididymis undergoing little if any enlargement. The cord and vas deferens are unaffected. There is little or no tenderness, and the peculiar sensation elicited by squeezing a healthy testicle is absent. The tunica albuginea is very greatly thickened. Hydrocele is

a frequent complication and tapping is often required to establish a diagnosis.

Cystic tumors of the testis closely resemble hydrocele, and differ chiefly in being opaque instead of translucent. Aspiration should be practiced before pronouncing positively upon their character.

Cancer of the testicle primarily invades the body of the gland, and almost invariably assumes the encephaloid form. Most observers doubt the existence of other varieties of malignant disease in this organ. The development of the disease is rapid. The patient has a sensation of weight, pain and dragging in the testis, the scrotum becomes distended, reddish or purplish, and the superficial veins are seen to be enlarged. The skin adheres to the gland, ulceration occurs, fungus protrudes, the inguinal glands are secondarily involved, and the patient by this time presents the characteristic cancerous cachexy.

3. In varicocele the tumor is knotty and irregular like a bag of worms, bluish in color; most frequent upon the left side; increases in size upon the application of heat; develops gradually; is dull on percussion; fluctuation doubtful; spermatic cord not affected; inguinal canal not involved. No cough impulse. It reduces spontaneously by any position that favors increased venous return, but returns immediately when the patient stands up notwithstanding pressure at the ring. There is weight and dragging in the scrotum.

4. In hæmatocele the advent is sudden; usually traumatic in origin; grows from below up if spontaneous; fluctuates until coagulation occurs; is at first soft, and hard after coagula form. It is pyriform in shape; ecchymotic; irreducible; heavy; dull on percussion. The spermatic cord is unaffected, and the inguinal canal empty. There is often pallor and prostration from loss of blood. The bowels are unaffected.

5. Bubo is seldom mistaken for a scrotal tumor, and it is unnecessary to name differential points.

6. An *undescended testicle* is painful, and pressure upon it yields a peculiar sickening sensation. It is found wanting upon the side occupied by the tumor, and the scrotum is imperfectly developed upon the same side. It is sometimes mistaken for a bubonocoele.

In order that it may not be thought that the somewhat minute enumeration of diagnostic points mentioned in connection with these various scrotal tumors is tedious or unnecessary, I beg to present the following cases which have fallen under my observation during the past few years. In all of them a more or less serious error of judgment occurred.

Case 1.—S. J. J., æt. 30. On Sept. 16, 1883, Mr. J. called upon me, stating that he was suffering from a hydrocele and wished a permanent cure; that he had consulted Dr. Roswell Park, who advised tapping it, but that as Dr. Park was about leaving the city, his family physician, Dr. Doering, advised him to place himself under my care for a radical cure. Mr. J. stated that when he was a boy while in swimming one day his attention was directed to the fact that the right side of the scrotum was larger and heavier than the left, but that he had never paid any attention to it until about a year previous to the time he

¹ The bacilli tuberculosis which were formerly probably disporting in the blood in a state of innocuous desuetude, now finding a fertile soil in the increased vascularization of the part, proceed to inhabit, multiply and take possession of the part to its ultimate destruction—just as other microbes have an affinity for the epiphysis of long bones where the blood current is sluggish.

called upon me, since which time he had noticed a gradual enlargement that caused no pain or discomfort except a sense of weight and a tired feeling in that side; but as it was steadily and slowly increasing in size he decided to have it removed. It was soft and fluctuant to the touch, pyriform in shape, slightly translucent; inguinal canal full and prominent, and from the history and physical appearance I concluded that it was a hydrocele complicated with a tumor connected with the testicle, and, having some doubt as to the exact nature of the growth, I took him to Dr. E. Andrews, who concurred in the opinion of a hydrocele and thought the tumor was possibly a sarcoma or cystic testicle, and advised emptying the tunica vaginalis and then examining the tumor more satisfactorily.

On Sept. 22 I aspirated the tunic in the presence and with the assistance of Dr. Roler, obtaining about two ounces of clear serum instead of a pint or more that I expected. I injected sac with 5 per cent solution of carbolic acid, and kept him in bed for a few days. I then concluded that the testicle was cystic and advised its removal, which was readily agreed to.

On Oct. 5, in the presence of Drs. Andrews, Doering, Beery, Stowell, and two or three students, I operated by making a long free incision down through the successive layers upon the tunica vaginalis, which I then loosened and raised up to examine more carefully. It was soft, fluctuant and opaque. I made a free incision into it, and instead of fluid out gushed a mass of omentum that had distended it, closely surrounding and masking the testicle. A small quantity of serum was present, an ounce or two perhaps. All doubt now disappeared and we had to deal with a case of incarcerated congenital omental hernia of the tunica vaginalis—the testicle was perfectly normal. The omental mass was tied in sections with catgut and cut off short, being left as a plug in the inguinal canal. All bleeding points were ligated with catgut. The testicle was returned within the tunic, a drainage-tube inserted, and the wound washed out with a carbolized solution and antiseptic dressing applied.

Mr. J. made a steady and uninterrupted recovery, resuming work in less than two months. The only complication was a circumscribed cellulitis extending along the cord, that appeared about two weeks after the operation, and was treated by hot poultices and blisters for some ten days, when the induration disappeared. I have seen the same complication in three other cases of operations upon the testicle, and believe it is a common occurrence. In this case the error was made of not attaching sufficient importance to the filling up of the inguinal canal.

Case 2.—S., æt. 29, a healthy young man, applied to me in August, 1881, for relief from a subacute epididymitis that came on a few weeks before as the result of a slight injury. It was treated by a suspensory, strapping and alterative ointments, but steadily and slowly enlarged until October, when it became nodular and fluctuant at two points, encroaching more and more upon and around the testicle. Dr. Gunn saw him about this time and opened an abscess, regarding it as a simple abscess of the

connective tissue and not involving the gland. It continued to discharge, the testicle increasing in size and the health of the patient declining until December, when a consultation was held. Drs. Gunn and Fenger advocated the removal of the diseased organ. Dr. Andrews favored temporizing. It was removed on January 11, 1882, and found to be tubercular. This operation was also followed by a circumscribed peritonitis and cellular induration along the cord. Prompt recovery followed, and he has enjoyed excellent health since.

Case 3.—Boy, æt. 8 years. I was called to reduce a strangulated hernia, when I found a simple hydrocele.

Case 4.—W., æt. 60. Had been troubled with an old inguinal hernia for years. On November 10, 1880, it came down and could not be returned. Four days later an operation was made, when, on opening the peritoneal sac, a cyst was found that had acted as a valve at the neck of the canal, preventing the return of the bowel by taxis. This condition was not suspected prior to the operation.

Case 5.—Chas. M., æt. 23. Had a right oblique inguinal hernia for ten years, supposed to have come from the kick of a horse. On February 6, 1883, it became strangulated. At the examination a large painful tumor was found. Within the external ring in the inguinal canal a smaller tumor was detected, which proved to be an undescended testicle. The gut was returned to the abdominal cavity, and as the testicle was useless and in the way of wearing an appropriate truss, it was removed. The young man made a good recovery.

Case 6.—J. W., æt. 46, had a congenital left inguinal hernia. On September 15, 1882, the bowel came down and became strangulated. Thirteen days later an operation was made, and a large mass of omentum and a knuckle of ileum found. These were returned, when the scrotum was found to be occupied by an immense hypertrophy of the cord and epididymis measuring eighteen inches in length and weighing twelve ounces. This was cut off and the stump tied at the ring. The patient died from exhaustion. This case is reported by Dr. John L. Atlee, and is certainly a rare complication.

Case 7.—In December, 1883, Dr. John Bell, of Benton Harbor, Mich., brought me a farmer, in consultation, who had multiple cysts of the cord. He had been treated by a quack for spermatorrhœa, said quack telling him that there were 478 cords running from his testicles to his heart, and if he had any operation done and a single one of those cords was wounded, instant death would ensue. I aspirated the cysts, and they have not refilled as yet.

Case 8.—Tuberculosis of testicle mistaken for cancer.

In conclusion I only desire to say that the diagnosis of scrotal tumors requires careful study and the employment of all the means at our command. No symptom should be lightly passed over and we should accept nothing on trust, but verify all statements ourselves. Diagnosis should be by exclusion.

A CASE OF CONGENITAL ABSENCE OF THE OSTIUM VAGINÆ, AND DELIVERY BY THE ANUS.¹

BY J. F. Y. PAINE, M.D.,

OF GALVESTON, TEXAS.

PROFESSOR OF MATERIA MEDICA, THERAPEUTICS AND HYGIENE IN THE MEDICAL DEPARTMENT OF TULANE UNIVERSITY, OF LOUISIANA, ETC.

"On April 24, 1885, late in the evening, I was called to attend Mrs. Hanna Thomas, who was suffering the pains of childbirth. Her age was 35, and she bore every outward sign of perfect physical development, and of being well nourished. I was told by the midwife that she had been in labor since the middle of the day preceding. The membranes had been ruptured early in the labor, and the patient was very much prostrated by her protracted and inefficient efforts to expel the foetus. The unsatisfactory progress caused her attendant to request the calling in of a physician.

"Examination developed an entire absence of the vaginal orifice, and passing my finger along the perineum, it sank into the distended anus, and encountered the foetal head just within the opening. The anus was dilated to about the diameter of three inches. Never having met with such a singular complication attending labor, I sought the advice and assistance of my friend Dr. J. F. Y. Paine."

The foregoing history is furnished by Dr. G. S. Sykes, the professional attendant of the case in question.

Examination confirmed the diagnosis of Dr. Sykes as to the absence of vaginal outlet, and revealed the presence of the foetal head within the rectum, arrested at the distended and resisting anus. A clammy skin, sighing respiration and rapid, feeble pulse, told the story of strength wasted by a fruitless labor. The uterus, exhausted by its unavailing efforts, was acting in the most feeble manner; the anus, though considerably dilated, was insufficiently so to admit the passage of the foetal head, and was rigid and unyielding. The indications were too clear to admit of a doubt as to the treatment. Chloroform was administered to the third degree, a Simpson's obstetrical forceps applied with comparatively little difficulty, and by moderate effort the head was promptly delivered. The shoulders and trunk were delivered by a *vis a tergo* exerted by squeezing and downward pressure on the uterus through the abdominal parietes. The placenta was speedily expelled by expression.

There was no apparent laceration of the anal sphincters. There was no unusual hæmorrhage at the time of her accouchement, nor was there subsequent oozing. Firm tonic contraction of the uterus quickly followed a dose of ergot. The anus regained its normal characteristics within a few hours. The subsequent treatment was conducted on general principles, viz.: rest in the recumbent posture, antiseptic irrigations per rectum, etc. There was nothing uncommon in her convalescence. She was able to sit up on the sixth day, and entered upon her accustomed domestic avocations at the end of the second week.

On the 8th of October, five months and sixteen

days after her accouchement, I was granted the privilege of a thorough examination, and found, as already stated, entire absence of the ostium vaginæ. All the parts within the vulva presented the characteristics of virginity—the clitoris was normally developed and situated; the vestibule and posterior commissure bore no signs of having been stretched, distorted, or lacerated by childbirth; the urethra was in its proper place; the nymphæ and labia majora were in every respect natural in their virginal symmetry of outline. Two fingers were readily introduced into the rectum and passed upward along the anterior rectal wall for a distance of about two inches, when it was clearly appreciable that the surface gradually sloped forwards and upwards and merged into the anterior vaginal wall, which at this point was natural in its anatomical relations. From a half to an inch below the *os uteri* could be distinctly felt the free edge of a membranous curtain, which represented the upper third of the recto-vaginal septum. There was nothing abnormal either in the size or position of the uterus, or in its relations to the vagina.

Examination with the speculum fully confirmed the revelations of the digital exploration. The most painstaking investigation failed to detect the slightest trace of cicatricial tissue. My conclusion was that the malformation was congenital.

This woman has borne three children, all at full term and well developed, but dead. The cause of death seemed to lie in the early drainage of the amniotic fluid, and the protracted labor. Nothing noteworthy occurred during either of her accouchements, except their continuance beyond ordinary limits and the exhaustion which, as a natural consequence, ensued. Her labors had lasted, she said, about two days; but had not in either instance been followed by fever, pain, abnormal discharge or other evidence of inflammatory action. Her convalescences had been uniformly short; sitting up on the sixth day, and resuming her ordinary duties at the end of the second week. Menstruation has always been regular (except during pregnancy) as to interval, duration and quantity lost, and painless. Sexual desire and its gratification during coitus was in every respect satisfactory. She had never been made aware, either by the exit of the menstrual flux, the method of sexual intercourse, or even the strange manner of her accouchements, that she was different from other women. Her husband, after being closely questioned, asserted most positively that he had never entertained the faintest suspicion that there was anything the matter with his wife, out of the usual order of things.

MEDICAL PROGRESS.

A CASE OF SHORTENING BY OPERATION THE BONES OF THE LIMBS IN THE TREATMENT OF INJURIES COMPLICATED WITH EXTENSIVE DESTRUCTION OF THE SOFT PARTS.—DR. MARTEL, of St. Malo, first conceived the idea, in 1882, that when extensive destruction of soft parts had taken place it would be better to reduce the bones to a corresponding

¹ Read in the Section on Obstetrics, at the Thirty-Seventh Annual Meeting of the American Medical Association.

length by resection than to rest satisfied merely with amputation. He was then attending a suitable case, but he was restrained from putting his idea into practice at that time, partly by the advice of a surgical friend, and partly by the untoward course of the case in question.

However, on June 2, 1885, a patient, B., æt. 32 was taken into hospital with a very severe compound fracture of the left leg. Anteriorly was a large wound whose extent was due to actual destruction rather than to retraction of the skin and subjacent tissues. The tibial fracture, oblique and not comminuted, was exposed in this wound, the ends overriding. The fibula was fractured in the middle.

The wound and its recesses were carefully washed with "strong" carbolic lotion, and afterwards, the limb was enveloped in a thick "*appareil ouaté*." The immobilization removed all pain. Reaction was moderate, (on the third day, evening, temp. 39.8.) Quinine for the fever; morphia and chloral for insomnia. Appetite returning. The remainder of the history is that of a suppurating, but not inflamed wound, with sloughs separating and cicatrization progressing up to February 25, (the fifty-fifth day of the treatment). On this day Dr. Martel resected about 75 millimètres of the tibial shaft, sawing obliquely both above and below. Much of the bone removed was necrosed. A corresponding portion of the fibula was removed through a separate opening. The two tibial fragments were sutured with a single stitch of thick silver wire, which does not appear to have held them very firmly together. The carbolic spray was used during the operation, and both during the operation and afterwards, the wound was carefully washed with "strong" carbolic lotion. Drainage with a large tube behind the fragment. Then carbolized charpie dressing and gutta-percha splints. On March 25 it is noted that "the osseous segments are united, but the uniting tissue is flexible." On or about this date the silver suture was removed from the bone. On April 25 "consolidation appeared complete." June 8 a fenestrated, silicated bandage was applied. August 3 "only two small lenticular" ulcerations remained, which soon afterwards healed completely.

The amount of shortening was 7 to 8 centimètres. There was a good deal of stiffness of the ankle joint. But otherwise everything was satisfactory; the limb was well shaped, and crutches and sticks were shortly discarded for a high boot.

The author is only cognizant of a single instance in which a surgeon was guided by an idea analogous to his own. In the *Centralblatt für Chirurgie* No. 50, 1884, Karl Loebker published a case in which, in order to facilitate apposition and suture of the ends of nerves and tendons, cicatrised and contracted after a transverse wound of the forearm, he resected portions of the radius and ulna. This operation was only moderately successful as regarded the ultimate results.

With regard to the question of what is the best time at which to undertake an operation like the author's he points out that, until sloughs have begun to separate, it is not possible to be certain of the

limits of destruction. After stating other considerations, he gives his opinion that the most favorable moment for resection is to be found between the tenth and twentieth day after the accident.—*Gaz. Méd. de Paris*, 1886. Feb. 27, March 13 and 20.

SEGMENTAL NEURITIS.—There appear to be good grounds for the division of neuritis into "interstitial" and "parenchymatous" varieties. The latter form has many causes, but the pathological anatomy, consisting in a series of modifications ending in atrophy of the nerve, presents but little variety in its characters, and has a close resemblance to the series of changes such as occur in the Wallerian degeneration of divided nerves. Apart from this form there is another, described first by Gombault, under the name of "*névrite segmentaire periaxile*." Guinea-pigs submitted to a process of slow poisoning by lead, without presenting any sign of localized or diffuse paralysis, yet became the subjects of a scattered neuritis of such a kind that one part of the length of a nerve fibre was inflamed, whilst the parts above and below it were in a normal condition; these disseminated patches sometimes occurred in more places than one on the same nerve fibre. Generally the alteration involves a single nerve segment, but it may transcend these limits or even be restricted to a portion of one segment. The process is of a genuine parenchymatous character, but affects only the myelin sheath and the protoplasm of the sheath, not the axis cylinder, which is never interrupted, and remains in relation with its centres; the nuclei multiply and the myelin undergoes segmentation. This form of neuritis is not special to guinea-pigs or to cases of chronic saturnism. It occurs also in man, and Gombault has observed it in the subjects of protopathic muscular atrophy, amyotrophic lateral sclerosis, and traumatic neuritis. He has also described it in a case of diphtheritic palsy, and in one which clinically resembled acute ascending paralysis. However, this periaxial segmental neuritis has not been frequently observed in further researches on the pathological anatomy of peripheral nerves, and since 1880 P. Meyer alone has given a description of its existence in a case of diphtheritic paralysis. In the *Archives de Neurologie*, No. 33, MM. Pitres and Vaillard—already well-known for their researches, especially on parenchymatous neuritis—have described an interesting case of pulmonary tuberculosis on which cutaneous diphtheria became grafted, and was followed by amblyopia, paralysis of the soft palate and limbs, with disorders of sensation, paresis of the diaphragm, irregularity of the heart's action, and death from pulmonary hæmorrhage; the brain and spinal cord were found to be healthy, but the peripheral nerves and spinal roots exhibited the changes indicative of the segmental form of neuritis. It has been shown by the same observers that peripheral neuritis occurs in tuberculosis, and they discuss the question of the dependence of the changes spoken of above on diphtheria or tuberculosis. For fuller information reference should be made to the valuable paper, which is illustrated by well-executed plates.—*Lancet*, June 12, 1886.

NITRO-GLYCERINE IN BRIGHT'S DISEASE.—The employment of nitro-glycerine in chronic renal disease, for the valuable service it renders in dispelling or moderating uræmic symptoms, is based upon the fact that high arterial tension is the constant concomitant of uræmia. How far it is desirable to habitually employ a remedy having so pronounced an action upon the circulation as nitro-glycerine is yet undetermined; but experience of its value in the diseases which are marked by abnormal arterial tension is accumulating. The latest contribution is by Dr. KINNICUTT, of New York (*Medical Record*, April 17, 1886), who has studied the effects of the drug in several cases, with results which harmonize with those obtained by Rossbach and Burzbinski, to which allusion is made. The continued employment of the drug in slightly increasing quantity does not only relieve headache, dyspnoea, palpitation, and other symptoms referable to the uræmic state, but is marked by an increase in the diurnal excretion of urine, together with a notable diminution in the amount of albumen in it. Cases are given where the albumen was noted quantitatively, and they show that in some the drug has a marked effect in its reduction. At the same time, as one case shows, there is often great variability in the albuminuria of chronic nephritis, which renders it important that similar observations should be made on a large scale before trustworthy conclusions can be arrived at. The amount of nitro-glycerine administered should be just within the limit of producing any subjective symptoms. Dr. Kinnicutt's conclusions may be given in his own words: "1. That in nitro-glycerine, given in small doses and frequently repeated, we possess a powerful agent in lowering the increased blood-pressure which is very constantly associated with the development of uræmic symptoms. 2. That it has the power to control or relieve many of the paroxysmal disturbances of the nervous system which are included under the general term of uræmia; of these, headache and asthma are especially benefited by its use, the relief being more marked and continuous than that obtainable either by opium or chloral. 3. That its influence upon the daily excretion of urine and serum-albumen in parenchymatous and interstitial nephritis is apparently to increase the former and diminish the latter. 4. That in the systematic and prolonged use of nitro-glycerine in appropriate doses, in chronic nephritis, we possess a means of maintaining more or less continuously a lowered blood-pressure, of often averting or relieving critical conditions, and thereby prolonging life."—*Lancet*, June 12, 1886.

ABORTIVE TREATMENT OF MAMMARY ABSCESS.—DR. LLEWELLYN ELIOT, of Washington, says: "About fifteen years ago I witnessed the beneficial effects of the free application of spirits of turpentine to abscesses and whitlows in their early stages. The result in each case in which such applications were employed was a drying up and disappearance of all traces of inflammatory or suppurative processes. From the earliest years of my professional life this has been a routine treatment with me, and arguing

from analogy, it has been adopted in cases of mammary abscess when seen in its incipency. The only disadvantage attending this treatment is the odor of the turpentine, which is of no importance when contrasted with the intense pain, sleepless nights and suffering accompanying suppuration of the gland.

"If upon the discovery of a drawing pain upon suckling, or a tender, hard spot in any part of the gland, the part be bathed with the spirits of turpentine, and then covered with a cloth, rag, or piece of flannel saturated with the same, we may, as a rule, look for the disappearance of the hardness, the tenderness, and all other uneasiness attending this troublesome affection, in the course of two, or at the most, three days. During the course of such a treatment the child may be nursed from the affected breast, but not as frequently as from the well one. It is hardly necessary to say that all traces of turpentine should be washed away before such nursing. The amount of milk secreted has never appeared lessened in the cases observed, nor have any of the ill results of the continued use of turpentine followed either in the mother or in the child.

"Whether this manner of dealing with this affection be in general use or not cannot be said, still there is no mention of it in many of the recent text-books on obstetrics. It is not claimed to be infallible, but its application will be attended with no bad results even if it be unsuccessful. Strapping, pressure, rest, applications of belladonna and soap-liniment, and the continuous application of an ice-bag, are among the various modes of treatment employed, but my faith now centres around the application of turpentine as an abortive of mammary abscess."—*Medical Record*, July 31, 1886.

SUGAR AND CORROSIVE SUBLIMATE AS A FIRST DRESSING IN WAR.—DR. HEIDENREICH, in a paper published in the *Vratch*, Nos. 19 and 20, strongly recommends as a first dressing on the field of battle a mixture of corrosive sublimate with powdered sugar in the proportion of 1 to 1000. It is important that when this is prepared the sublimate should be evenly distributed, and this is easily affected by first dissolving the mercurial salt in a little spirit and then carefully rubbing up the sugar with it. The spirit ultimately evaporates and leaves a powdered mass of uniform composition. A little packet is supplied to each soldier, containing a capsule in which is 5 grammes of the mixed powder—i.e., $\frac{1}{200}$ of a gramme of sublimate—for the purpose of sprinkling on the wound; also a good-sized piece of gauze impregnated with $\frac{1}{3}$ per cent. of its own weight of sublimate by means of Bergmann's process, which consists of dipping it in a solution containing 10 parts sublimate to 500 glycerine, 1000 alcohol, and 1500 water. Some hygroscopic wadding is also supplied, and this, when enclosed between two folds of the gauze, forms a dressing measuring 650 sq. centim., which is large enough to cover a somewhat extensive wound. The whole is enclosed by means of a layer of varnished paper and a triangular bandage, which is fastened with two safety pins. The author claims for this mixture of sugar and sublimate the advantage of being

a particularly powerful antiseptic and quite innocuous. Sugar, he says, is the best substance for diluting the sublimate, being itself somewhat antiseptic. This dressing has also the additional advantage of being suitable for use wherever water may be procurable. This, of course, is not always the case, and where it is the source is frequently in a marsh or pool of anything but hygienic appearance. Under these circumstances he advises that filtration should be resorted to, and consequently proposes that a kind of filter consisting of flannel impregnated with sublimate should be included in the packets supplied to the men. The whole contents of the packet weigh only 75 grammes, and are exceedingly portable and inexpensive.—*Lancet*, June 12, 1886.

THE DIAGNOSIS OF TUBERCULAR DISEASE OF THE URINARY ORGANS.—DR. IRSAL, in the *Wien. Med. Presse* (No 36, 1884) records two cases in which tubercular disease of the kidney was diagnosed from the presence of Koch's bacilli in the urine, the diagnosis being confirmed by *post-mortem* examination.

M. de Gennes (*Ann. des mal. des org. génito-urin.*, September, 1885), says that the discovery of tubercular bacilli in the urine is difficult, partly because centres of tubercular disease are often present in the kidneys for a long time without discharging their contents into the urine, and partly because of the excessive dilution of the bacilli in the urine. Hence, one may not find the bacilli in the urine, although the urinary organs are the seat of tubercular disease; but on the other hand, one must not mistake for Koch's bacillus any of the many bacteria which grow in altered urine. It is necessary, therefore, to examine only the sediment of the urine after it has stood for several hours, and in the examination to be careful to declorize with nitric acid very thoroughly. Even with these precautions, and after examining numerous specimens, it is rare to meet with more than two or three bacilli. He has in five cases of cystitis, however, determined the tubercular nature of the disease by finding the bacilli in the urine, while there was no other evidence of tubercular disease in the cases. His conclusions are, that just as in the case of the lungs, so in the case of the urine, if one finds no bacilli, one cannot infer that there is no tubercular disease; but, if one finds even a single bacillus, of the nature of which one is absolutely certain, then the diagnosis of tubercular disease is affirmed.—*Revue des Sciences Médicales*, Jan., 1886.—*Glasgow Medical Journal*, May, 1886.

QUININE FOR TRAUMATIC NEURALGIA.—In a note on this subject Mr. F. J. HART says:

That quinine cures neuralgia, especially of the asthenic type, is a matter of ancient history, but it is not so generally recognized that it is useful in the following severe injuries:

CASE 1.—This was a case of dislocation of shoulder by direct violence, with great bruising. After reduction, agonizing pain set in, following the course of the brachial plexus. It was compared by the patient to the "gnawing of a dog." Sleep was quite banished. Chloral and opium, in full dose, gave no

relief. A 5-grain dose of quinine, however, gave almost instant ease, with some hours' sleep; and, although the pain returned, it was always controlled in the most remarkable manner by the quinine. Only three or four doses of the remedy were required.

CASE 2.—In a severe wrench of the shoulder, with rupture of muscular fibres, attended with great pain, especially at night, relief was quickly obtained by 4-grain doses of quinine, given every six hours. The patient described the effect of the medicine as most rapid and soothing.

CASE 3 was one of a fall from a ladder, producing fractured rib and contusions. There was great pain, "not one wink of sleep," in spite of chloral (gr. 25) and opium (1 gr). The patient was very violent and excitable. A fourth of a grain of morphine, hypodermically injected, calmed him somewhat; but the pain returned, and as I did not wish to push the opium, his kidneys being defective, I substituted 2 gr. of quinine ever four hours. After this, he got much better, and confessed that he could bear easily the little pain which remained. All these patients were full-grown men.—*British Medical Journal*, June 5, 1886.

RE-INJECTION OF BLOOD DURING AMPUTATION AT THE HIP-JOINT WITH RAPID RECOVERY.—By A. G. MILLER, M.D., Edinburgh. In a case of strumous disease affecting both hips, the left knee and the left elbow, with a large abscess connected with the left hip, the patient being in very feeble condition, amputation at the latter joint became necessary. The limb having been exsanguinated to the middle of the thigh, and a powerful elastic tourniquet applied at the groin, a rapid circular cut was made right down to the bone in the upper part of the thigh, the femur sawn through, the femoral artery and some smaller vessels tied, and the tourniquet removed; some hæmorrhage still occurring from a few small vessels, they were also ligatured. All the blood which escaped, both from the femoral artery and the smaller vessels, amounting to eleven ounces, was caught in a vessel containing a solution of phosphate of soda and re-injected into the deep femoral vein. By an incision on the outer side of the thigh the head of the femur was then dissected out. The wound was dressed antiseptically. The patient suffered no shock whatever, nor depression of temperature after the operation. For the first few days, he was flushed and had a fuller pulse than before the operation, but he had no rise of temperature. The weakness and the anæmia of the patient, together with the increased vascularity of the parts due to the disease, rendered it very likely that he would not have survived the operation, had not the greater part of the blood lost been re-injected—the fact being that from the exsanguification of the leg, together with the reinfusion, there was probably an ultimate gain of blood after the operation.—*Edinburgh Med. Jour.*, February, 1886.—*Annals of Surgery*, 1886.

COAGULATION OF THE BLOOD.—In a short paper with the above title, DR. ERNST FREUND relates the results of his experiments undertaken to show the effect

of oil in hindering the coagulation of the blood after it is withdrawn from the body. Blood from the carotid of a dog collected under oil remained fluid at ordinary temperatures for twenty-four hours; as did also blood which had been poured into glass vessels whose walls had been smeared with vaseline. In the latter case coagulation did not ensue even if the blood were stirred with an oiled glass rod, although it took place in a few minutes if the blood were poured into an unoled vessel, or were stirred with a dry glass rod. If blood caught in this way were prevented from drying, and if contamination with dust was prevented, coagulation might be prevented for several days, during which the corpuscles sank to the bottom, leaving the clear plasma on the surface. Similar observations were made with oiled cannulæ and tubes, in which the blood remained fluid. As the result of his experiments the author comes to the conclusion that, as on the one hand the absence of adhesion of the blood to the walls of the vessels prevents coagulation, so, on the other, if any adhesion is allowed, after the blood is drawn from the body, this acts as the starting-point of the coagulation.—*Medizin. Jahrbücher*, Heft. i, 1886, page 46.—*Glasgow Medical Journal*, May, 1886.

TUBERCLE BACILLI IN ADDISON'S DISEASE.—It has long been held by some writers that the fibro-caseous change which characterizes the suprarenal bodies in Addison's disease is of tubercular nature, and the histological characters upon which this opinion rests have been strengthened by the detection of the bacillus tuberculosis in the morbid material. For this observation pathology is indebted to Herr Goldenblum, of Dorpat, in a well-marked case of the disease which he examined in 1884. The subject was a man 24 years of age; there was well-marked bronzing of the skin and mucous membranes, caseation of both suprarenals, general wasting, pulmonary emphysema, cloudy swelling of the heart fibres, liver, and kidneys, and swelling of the intestinal solitary glands and the portal lymphatic glands. At Professor Thomas's suggestion the diseased capsules were examined by Ehrlich's method, and large quantities of tubercle bacilli found in the caseous masses (Virchow's *Archiv*, Bd. 104, s. 393). Although Guttmann in 1885, and Rausenbach in the present year, have reported cases of suprarenal bacillary tuberculosis, yet in neither case were symptoms of Addison's disease prominent, and both these cases must yield priority to Goldenblum's. He remarks that on the bacillary test his case goes to prove that in Addison's disease, in which the capsules are the only organs that exhibit caseation, the lesion must be regarded as a local tuberculosis, unless it can be proved that the occurrence of the bacilli is a secondary event.—*Lancet*, June 12, 1886.

INTUBATION OF THE LARYNX.—In a report of the Chicago Medical Society, Dr. Strong describes a successful case in which a No. 2 O'Dwyer's tube was kept in a child's larynx for sixty-eight hours. The affection was acute catarrhal laryngitis.

At the same meeting Dr. Waxham stated that he

had often used tubes, and spoke of seventeen cases, with eight recoveries. It is important to note that Dr. Waxham had used them in cases of diphtheria.

Dr. Allan, Glasgow, in *Outlines of Infectious Diseases* (Churchill, 1886), refers to the use of tubage in the treatment of diphtheria, and recommends Macewen's tubes as a valuable method of treatment.

Considering the unsatisfactory state of our therapeutics in diseases of the larynx accompanied by membranes, and the frequent necessity of operative interference, the results of those who have tried tubage must be carefully noted. There can be little doubt that tubes will prove invaluable in many conditions of the larynx when asphyxia is threatened. It would perhaps be right to say, however, that most surgeons express considerable doubt as to the efficacy of tubage in conditions associated with the formation of membranes (particularly in diphtheria), and hence such cases as the above rather indicate a more extensive trial of this operative method.—*Glasgow Medical Journal*, May, 1886.

ALBUMINATES IN MILK.—SEBELIEN describes in the *Zeitschrift für phys. Chemie*, vol. ix. p. 444, two new albuminates of milk besides caseine, viz., lactoglobulin and lactoalbumen.

1. To obtain lactoglobulin, the milk is first carefully neutralized with soda lye, in case it be of an acid reaction, and then saturated with chloride of sodium. The filtrate on being warmed produces a flocculent precipitate, which consists principally of phosphate of lime; the filtrate of this, on being saturated with sulphate of magnesium, precipitates lactoglobulin. The percentage of lactoglobulin in milk is very small.

2. Lactoalbumen is obtained by adding one-fourth per cent. of acetic acid to the filtrate of milk, mixed with sulphate of magnesium. By solution in water, dialysis, precipitation of the remaining solution through alcohol, and washing with alcohol and ether, lactoalbumen can be obtained as a white powder, wholly soluble in water. Lactoalbumen is by no means identical with serum albumen, and differs from caseine in containing a higher percentage of sulphur (the former having fourteen per cent., the latter seven per cent.), and a lesser percentage of phosphorus.—*Therapeutic Gazette*, June 15, 1886.

SALOL.—PROFESSOR VON NENCKI, of Berne, has discovered a new antiseptic, to which he has applied this name. It is a whitish aromatic substance, insoluble in water, but soluble in alcohol. It is highly recommended as a substitute for the salicylate of sodium in the treatment of acute rheumatism, as it is alleged that it does not cause the nausea and other unpleasant effects of the latter salt, and is more rapid in its action. It is a valuable antipyretic in phthisis. As an antiseptic it is said to be of value in the treatment of intestinal catarrh, typhoid fever, and cholera. From the fact that it prevents urine from decomposing, it is suggested as a local application in vesical catarrh. As a powder suitable for sprinkling over wounded and ulcerated surfaces it is said to possess all the antiseptic properties of iodoform without its disagreeable odor.—*N. Y. Medical Journal*.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

THE DIAGNOSIS OF INFECTIOUS DISEASES.

At a recent meeting of the New York County Medical Association, PROFESSOR E. G. JANEWAY, the worthy successor of the late Professor Austin Flint in Bellevue Medical College, read a paper on "Certain Points in the Diagnosis of Some of the Infectious Diseases." In the preparation of this paper he was able to bring to his aid his large experience in private and hospital practice, especially that gained by a several years' service as one of the Health Commissioners of New York City.

In speaking of smallpox Dr. Janeway said that he had known the beginning of a considerable outbreak of the disease to be traced to a single mistake in diagnosis. He thought that one of the greatest safeguards against an error in diagnosis as regards smallpox, consisted in having such a classification of the affection fixed in the mind as should seem to take account of the various methods of its manifestation. From many of the text books important facts bearing on the method of development of certain forms of the disease are omitted; and he suggests the following classification as convenient: 1. Purpura variolosa. 2. Variola vera. (a) Confluent; (b) Discrete; (c) Corymbosæ; (d) Hæmorrhagic. 3. Varioloid. 4. Variola varicelloides. The distinction between purpura variolosa and the ordinary hæmorrhage type, where the blood is extravasated with the vesicles, should be kept in mind, and this is best accomplished by making such a classification as the one given. Many have failed to recognize or to have any knowledge of the existence of this form; and many errors of diagnosis must be attributed to this. One great danger is in making mistakes between this disease and a malignant type of some other infectious dis-

eases. The full history of the case should be obtained; the possibility of a visit to a strange place, the getting of some cloths, etc., may furnish a clue in the absence of other clue. As an illustrative case he cited one to which he was called in another city, to decide as to the nature of a strange variety of fever. One patient had already died, and a second was seriously ill with it. He found the latter sitting up in bed, with a weak pulse, though with but little febrile movement, and suffering with dyspnoea which appeared to be due to changes in the blood. There were purpuric spots over the chest, abdomen and legs, and in one place there was a small vesicle, of no determinate character; but nowhere were there any papules or umbilicated vesicles. He suggested that the disease was probably purpura variolosa, and this opinion was confirmed, *first*, by learning that the patient had attended the one who died (the fatal issue taking place about twelve days before the beginning of his own sickness); and *secondly*, several of those who had been exposed during the sickness and at the funeral of the first patient were down with the fever; and that at least one of these had an eruption which proved to be discrete smallpox. This case, he thought, illustrated three points in establishing a diagnosis: 1. It is important to know the nature of the disease from which a malignant case, itself not possessing positive features, has developed. 2. Should the patient have died this may be done by an investigation of others exposed to the original case; these having perhaps a milder and more characteristic type of the malady. 3. The result of exposure to the malignant case may in some instances be a proof of the nature of the disease. He was particular to emphasize that we must not be content to simply consider the eruption and the patient's condition, but must use every means in our power to establish a correct opinion as to the nature of the disease producing this state which is demonstrated purpuric or malignant. He also introduced a case to illustrate the importance of sometimes making an autopsy to decide the nature of a doubtful disease.

Mistakes between smallpox and scarlatina may occur in those cases of variola in which a marked red efflorescence first occurs, followed by darker spots and papules, and finally by vesicles. In some cases petechiæ appear in places, and hæmorrhages follow; and not infrequently in severe cases the vesicles may appear first on the inner aspects of the thighs and in the axillary spaces, the face being free. As the throat may be sore at this time as a result of the eruption, a mistake may be made if the order of events be not kept in mind. Such mistakes

have been made in these cases as considering the vesicles sudamina. One point to be remembered is, that an examination which omits an inspection of the abdomen and chest, and particularly of the inguinal and axillary regions, may lead to a mistaken opinion in the case of a severe infectious disease.

In regard to measles there may be a two-fold mistake: On the one hand the first stages of the small-pox eruption, prior to the formation of the vesicles, may lead one who looks hurriedly at the case, and does not consider the invasion symptoms, to diagnose measles. The other mistake occurs when one looks at a severe case with a red skin, and in it a number of dark maculo-papules, together with hæmorrhages of larger extent, and hæmorrhages from other places, as the nose. One who sees the first stage may consider it as scarlatina; while a little later the numerous papules may lead to a mistaken diagnosis of black measles.

The mistake of considering syphilitic eruptions as variola is more common than the reverse. Most of these mistakes are the result of want of close observation of the whole eruption, together with a consideration of the history of the case. The multiformity of the rash, the condition of the glands, and the duration of the disease should determine in a large number of cases the correct diagnosis; to which the history adds confirmatory evidence. In Dr. Jane-way's experience syphilis causes more mistakes than other disease except measles. An additional point in the diagnosis is the absence of the eruption on the hands and feet, and in the mouth in cases of syphilitic pustular eruption, otherwise pretty generally distributed over the body.

In speaking of variola and varicella he well remarked that students may be puzzled by finding opposing statements regarding the varicellous eruption, not only in different text-books, but sometimes also in different parts of the same work. The danger in mistaking varicella lies in attending too closely to the eruption, for at times a slight induration is met with at the base of some of the pits of varicella, due to irritation. A careful search will generally show on the back and buttocks, as well as behind the ears, characteristic spots; while in other places the eruption may be more or less altered. In doubtful cases attention should be paid to the cause of the attack, if known, and to the time of the development of the eruption after the patient was taken sick. Dr. Jane-way has known of several cases of variola contracted from cases which had been pronounced varicella by careful examiners. In varioloid he had met several cases of varicella-like eruption; so that he believed

in making a subdivision of the diseases which should include this, under the head of variola varicelloides.

Typhus fever, when well-marked and with the characteristic eruption, causes little trouble in diagnosis. The earliest cases of an outbreak are, however, not always so well developed, and consequently, the disease may gain headway. In children, particularly, there may be great difficulty in deciding between typhoid and typhus. If we could study a number of cases, we might find the average duration an aid in diagnosis; but this applies more especially to the case of adults. A fever the great number of cases of which terminate (many of them comparatively suddenly) between the eleventh and fourteenth days, should always raise the suspicion of typhus. An autopsy should always be made as a sanitary necessity (should the opportunity occur) to decide the nature of a doubtful outbreak of fever. The lesions of typhoid are characteristic, while those of typhus are in some respects negative; but, in practice, if one of a number of cases of fever which has lasted longer than a week should present, on autopsy, only an enlarged spleen, with minute hæmorrhages on the serous membranes and parenchymatous degeneration of the liver and kidneys, we should feel justified in considering it due to typhus in this climate. Where isolated cases are concerned, it is advisable to examine the intestinal mucosa and the muscles, so that trichinosis may be excluded. We should attach great value to an examination as to the nature of the disease occurring in other inmates of the house, or among the friends of a fever patient, as an early aid in deciding upon the true cause of a case of fever. The neglect of this has often led to serious results. We may admit that typhoid fever may occur with typhus; but, in practice, two or more persons exposed to the same cause of fever should, if becoming sick with a febrile complaint, notwithstanding certain differences in the manifestations, be considered as having the same disease. This is an important point, because, owing to some differences in the eruption and certain minor details, physicians have at times been told that of two members of a family sick, one had typhus, and the other typhoid fever.

The use of antipyrin may cause the appearance of a profuse, measly rash, which may lead the physician in attendance to suppose what he has primarily considered typhoid to be a case of typhus. As regards diarrhoea, all practitioners know that not a few cases of typhoid run their course without it; and, again, it may occur in typhus, although the stools have not the peculiar character of those of typhoid. Typhus fever is not only likely to be considered typhoid, but

also to be mistaken for cerebral inflammation, and particularly for cerebro-spinal meningitis, on account of a peculiar petechial rash in the latter. In doubtful cases optic neuritis, if present, will decide in favor of cerebro-spinal inflammation. But, notwithstanding the fact that Dr. Janeway had had a considerable experience with cerebro-spinal fever, he had not as yet seen a single case in which the rash resembled that of typhus. Moreover, we very frequently meet with herpes of the face and lips in cerebro-spinal disease; but so rarely in typhus and typhoid fevers as practically to amount to an almost pathognomonic sign against these affections, if present in a doubtful case. It may occur in so many other conditions, however, that its presence is of no diagnostic value, except as against the probability of either typhus or typhoid. Flea-bites occurring in typhoid fever have in some cases caused a diagnosis of typhus.

Tuberculosis is a condition which causes not a few mistakes in the diagnosis of typhoid fever, and, at times, of typhus also. Meningitis is so rare a complication of typhus or typhoid that its existence should always raise the suspicion of another process, and more particularly of tuberculosis. If choked disc be found on ophthalmoscopic examination, it will still further increase the probability of this affection. The next step is to ascertain if at any point of the body there is a tubercular lesion accessible to proof or strong suspicion; or if from the previous history there is any probability of such a condition of the lungs. It should be remembered that examination of the lungs in unconscious, and particularly in comatose, conditions is extremely unsatisfactory; and very good examiners have supposed the lungs to be in health when making examinations in such states, while in reality they were the seat of advanced phthisical processes. If decided proof should exist, on examination, that the lungs are the site of disease which, from its position, may be assumed to be tubercular, then it would, with the foregoing facts, be violence to evidence to call the disease typhus or typhoid, unless absolute proof of the presence of one of them could be obtained; as, for example, by the characteristic eruption of typhus.

Some suppose that the finding of bacilli in the sputa will invariably decide the question between typhoid fever and tuberculosis. If the examination be made with care, and every precaution be taken in collecting the sputa to be certain that there is no contamination of the vessel or of the sputa after collection, then the presence of indisputable bacilli would be proof. But if it be supposed that anyone could make the examination and decide, and if the

usual manner of collecting sputa be employed, there are undoubtedly chances for error. Again, bacilli might not be found in the sputa, because of lack of care in selecting the proper portions for examination, and in some cases as a result of employing the short method for staining. While Dr. Janeway has been able to make some very good diagnoses by this means, he has met with cases in which phthisis had been diagnosticated from finding a few bacilli; yet the subsequent course of the disease, or an autopsy, disproved the diagnosis. There are certain things which a hasty observer may mistake for bacilli, such as small crystals which appear red as the light is refracted in passing through them, insufficiently decolorized bacteria of other kinds, etc. But both typhus and typhoid fever may coexist with phthisis.

Pyæmia, more particularly that dependent on otitis media and bacterial thrombosis of the lateral sinuses, also causes mistakes in diagnosis, as against typhus and typhoid fever. The reason for this is that, in the unconscious or delirious state in which patients thus affected may come under observation in hospital practice, no mention is made of the old ear trouble, and no examination of the ear is likely to be made. The irregularity of the form, the not infrequent coexistence of meningitis or cerebral abscess, with phenomena more or less suggestive of these conditions, the history or personal observation of suppurative discharge from the ear, and that it had perhaps become foul or been arrested, tenderness or œdema over the mastoid process, and the observation of abscesses in the cellular tissue or of joint inflammation, should at once lead to a probable diagnosis of otitis media. In one case related, the patient being a woman suffering from some fever of doubtful nature, Dr. Janeway found as a useful aid to diagnosis thrombosis of the internal jugular vein, giving a firm feel to the vessel. During a year he has met with three cases of this malady, and in one the thrombosis of the lateral sinus was not of a completely obstructive nature, so that œdema behind the ear was absent. In a suspected case, jaundice will point towards pyæmia or septicæmia, as distinguished from the fevers in which its occurrence is comparatively rare; and such jaundice was present in one of the three cases referred to.

INTERNATIONAL MEDICAL CONGRESS.

In another department may be found "Circular No. 2," concerning the Ninth International Medical Congress, containing important information to the medical profession in this country and abroad. As

it is practically impossible for the Executive Committee to personally give this information to the profession, it is hoped that our exchanges will further the objects and work of the Committee and of the Congress by reprinting the circular.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, Wednesday, April 14, 1886.

THE VICE-PRESIDENT, W. H. TAYLOR, M.D., IN THE CHAIR.

DR. J. FORD THOMPSON reported a

CASE OF LITHOTOMY, WITH SPECIMENS.

The case was turned over to him by Dr. Hagner, who had suspected stone from the symptoms.

Wm. M., aged 64, had been suffering from well-marked vesical symptoms for fifteen months, but had been somewhat of a sufferer for a longer time. Examination by sound at once detected stone. He at first intended to do lithotripsy, and had enlarged an abnormally small meatus with that operation in view. He found the urethra, however, so small that it would be impossible to pass a good-sized lithotrite, so he abandoned rapid lithotripsy. Thinking that the calculus or calculi were small, he decided on the median lithotomy operation. On April 3, assisted by Drs. Hagner, G. W. Johnston and Cutts, the patient was anesthetized, the bladder washed out and left full of warm water; the grooved staff was passed and the bladder was quickly and easily reached by the median line incision. On passing the stone-forceps a calculus was at once grasped, but it was found to be too large to be drawn out through the opening. A stronger pair of forceps were then introduced and the stone was broken and removed in sections. Other calculi presenting, also too large to be removed with the existing opening, it was enlarged by a lateral incision into the prostate gland. Two large calculi were now removed, with portions of one or two others, which emptied the bladder. There having been very little hæmorrhage and that having stopped, the patient was put to bed, leaving the wound open. The weight of the four calculi was 493 grains. The patient was making an excellent recovery. The urine was voided through the opening, but had been under the control of the patient from the first. Several times he had passed a small quantity of bloody urine by the natural channel, and on two occasions a sound had been passed the same way.

Dr. Thompson said there were two points of especial interest in this case. He had stated some time ago that lithotomy was much less used than formerly, and then chiefly on children. Here was a case where lithotripsy was out of the question owing to the un-

usually small size of the urethra. He did not think that strictures were the cause of this, as there was nothing in the history to give ground for that belief.

The *second* point was the question whether the median or lateral incision should be made. He had been deceived in this case about the size of the stones, as the bladder was so completely contracted around them that he could hardly move the sound about. Most surgeons prefer the lateral incision, but the median was the easiest and in his practice had been followed by the best results. The supra-pubic operation was undoubtedly the best where there was a large stone, and was preferred by many good men when lithotripsy was not applicable. Either the median or lateral operation may be followed by impotence; hence they should not be done on young men. In the supra-pubic operation it is absolutely necessary that the bladder be above the pubes. With this in view the bladder is filled with water, or a rubber bulb is introduced and then blown up; and lately he had seen a report where the calculus had been seized by a lithotrite and pushed up against the fundus of bladder. Dr. Thompson does not believe in leaving a catheter in the bladder in any case. He thinks it better to use it as required. In the case reported the temperature had never gone above 101°, and that was on afternoon of day of operation. At present the wound was granulating nicely and a good recovery was certain.¹

THE CONSERVATIVE ELEMENT IN DISEASE.

DR. A. F. A. KING recapitulated some of the points considered in his paper read on April 7 (*JOURNAL*, June 5, p. 636), and proceeded, in accordance with the principles then declared, to present a provisional explanation of the *phenomena of fever* and their utility in contributing to preserve life. During an extensive acute inflammation, a pneumonia for example, which was simply a *non-traumatic* injury made by *invisible* weapons, or during a real traumatic injury made by visible violence, we immediately observed a new appropriation and distribution of nerve force—the appropriation made under normal conditions for maintaining the assimilative and digestive industries was now, as it were, recalled, and expended in repairing the injury. But, as the nervous centres must still be fed, and their functions maintained without interruption, and as metabolism of matter must still be continued to evolve force, dissimilation of fat and muscle (hence “wasting”) must take the place of food pabulum. But this tissue-change produces excessive heat, which, however, is reduced by increased frequency of the heart's action, throwing the blood to the skin (which last thus becomes red and hot), and to the pulmonary vesicular mucous membrane (which is 1,400 square feet in area), where, and by which, blood refrigeration may be secured. The respiratory motions, during fever, are also increased in frequency and thus cool air is taken more plentifully into the lungs.

Again, the desires of the fever patient to bathe in and drink cold water, and which must always be con-

¹ April 29. Dr. Thompson reports the above case under this date as being perfectly cured.

sidered a part of the disease, are again designed for blood refrigeration, with other important uses. In brief, the sequence of events may be thus stated:

1. The injury.
2. Anorexia and arrest of digestive industries; arrest of muscular exercise and intellectual labor, the vital forces ordinarily used for these purposes being now appropriated to repair the injury.
3. In the absence of food supply, waste of tissue must be increased to evolve force by which the functions of the nerve centres, heart, etc., may be maintained.
4. Waste of tissue evolves excessive heat.
5. The phenomena (above described) for refrigeration reduce the heat, and so tend to preserve life.

In the hectic fever of consumption, it would probably not be far wrong to consider it as resulting from the (to use a figurative expression) disassimilating kitchens of the body, preparing an evening meal of force and material for the all-important nerve centres. It was questionable whether any of the various pills and mixtures given to relieve hectic fever, in such cases, had prolonged, positively, the lives of consumptives, even if the hectic were controlled by them, which was again doubtful.

If these views, stated tentatively, were correct, it would seem within the range of possibility to forestall the phenomena of fever by injecting nutritive fluids into the veins. Should our manufacturing chemists, who have of late produced so many organic compounds artificially, learn to manufacture a good imitation of *chyle*, and should the ingenuity of our surgeons provide an easy and harmless method of venous infusion, by constructing a sort of artificial *thoracic duct*, to be placed in a vein of the arm, we might then, perhaps, introduce a proper quantity of nutritive pabulum into the blood, two or three times a day, to prevent fever waste and fever heat, and still maintain the functions of the central nervous system. Dr. F. B. Harrington had recently (as we have seen in the journals) introduced on two several occasions, respectively, 3xxx and 3xxxvi of a saline solution into the median cephalic vein of a woman almost dead from hæmorrhage, with a favorable result. Why could not an artificial chyle be infused in the same manner?

Dr. King further remarked that the term "disease" embraced so wide a field, and such a vast variety of pathological phenomena, that it would be impossible to present the subject intelligibly and satisfactorily without an entirely new classification of morbid processes and the employment of many new terms. With relation to the want of conservatism in malignant growths, this might be explained by their not being under nervous control. In uterine cancer, for example, after the climacteric, and when it is natural for reproduction and sexual function to cease, the nerves probably atrophy, or suspend for the most part their vaso-motor control, and thus the histological growth in the uterus becomes a histological riot, governed only by "mob law," and without any benign purpose. When the reproductive factory has stopped work, and its offices are empty, the nerve telegraph and telephone are, as it were, taken down, for the

sake of economy, and after then any artificially produced growth grows like a fungous excrescence, each cell taking care of itself, without any regard for the laws that respect and protect the entire fabric of the body.

At the very beginning of a study of this sort it could hardly be expected that he, or any one else, should be able, all at once, to explain the conservative influence of many pathological processes of which, at present, we did not even know *positively* the *cause*, which last was the first thing to be learned in order that the utility of the results might be ascertained. All he could hope to accomplish was, to entice the minds of pathologists, students and clinicians into the direction of inquiring, in any case of disease, as to the designed purpose of the observed phenomena. We must ask ourselves: What is this organism trying to do? Why does it do so? What is the use of the changes of function and structure? Are they, or are they not, advisable, *under the circumstances that produce them*, to maintain life? In a word, we must study the *physiology of disease*.

DR. BERMANN said that the question of the conservatism of fever had been under discussion for many years, and that in some cases that was its acknowledged function. Dr. King had, however, left out all mention of the germ theory of disease, as in pneumonia, febris intermittens, etc. If we can take the ground that fever is an effort of the economy to oxidize the germ, well and good, and this appears to be the case in trichinosis, where, after several weeks of high temperature, the trichinæ become surrounded by a deposit of lime and are made harmless. He does not agree with Dr. King as to the value of the hectic fever in phthisis. In his opinion septic fever is the name for it. He also doubts the hypertrophy of the uterine nerves during pregnancy. This has never been proved either as regards size or number of nerves. If they did increase in either way he failed to see how innervation took place. Certainly there was never complete atrophy of them.

DR. REYBURN said that Dr. King's subject was an interesting one and that he was not alone in his belief. Graves, Bennet and Chambers had all written on this subject. For instance, in pneumonia the fever seemed to be an effort of nature to remove the detritus from tissue waste, and that now it was the custom to feed our patients in fever. If we want to treat our patients on scientific principles it must be more on this line and less pill and physic giving. Fevers must not always be cut short. He thought it well in all societies to discuss these questions and to make our practice more on this basis.

DR. KING said that he was not prepared to explain the conservatism of disease in every case. He had been aware all along that the germ theory of disease would be a stumbling-block, but he hoped that eventually all would be satisfactorily explained. As for pneumonia, which Dr. Bermann had said was from a germ, he did not believe that this had been proved. At all events *he* was not ready to accept it. His assertion that the nerves of the uterus were hypertrophied during pregnancy was obtained from text-books by the best writers and not from his per-

sonal observation. He said he thought it rational to believe that there was hypertrophy of nerves in the hypertrophied muscle of the athlete, and he did not see why the same would not apply to the pregnant uterus.

DR. ACKER said that antipyrin, contrary to Dr. King's assertion that the hectic of phthisis could not be controlled, would bring the temperature of such cases down.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, July 19, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. D. A. K. STEELE read a paper on

THE DIFFERENTIAL DIAGNOSIS OF SCROTAL TUMORS.

(See page 173.)

DR. CHRISTIAN FENGER agreed with Dr. Steele that gonorrhoea in itself has nothing to do with tuberculosis; that it will not cause local tuberculosis of the epididymis any more than a trauma will cause local tuberculosis anywhere else in the body. When there is tuberculosis in the body somewhere, and consequently tubercle-bacilli in the current of the blood, then it may be that the local inflammation from gonorrhoeal epididymitis, just as extravasation of the blood from a trauma, favors the accumulation of tubercle-bacilli in those places. Occasionally local tuberculosis will commence in an inflamed epididymis, but in a large number of these cases of scrotal tuberculosis there has really been no gonorrhoeic epididymitis preceding.

DR. W. T. BELFIELD thought that too much stress had been laid upon the history as a means of differential diagnosis between syphilitic and other enlargements of the testicle; when affirmative, the history is a valuable factor; when negative, the diagnosis must be made without regard to the history. He mentioned a case where there was not only no history of syphilis, but also a nodular enlargement of the epididymis with but slight increase in the size of the testis—features usually characteristic of tuberculosis; yet the patient's age (31) argued so strongly against tuberculosis that it was determined to try syphilitic remedies before proposing excision; the effect was immediate and complete. Primary tuberculosis of the genital organs is evidently an infection from within—hæmatogenous. The idea of local infection through intercourse with a subject of uterine or ovarian tuberculosis is of course fanciful; indeed, very many of these patients are boys just beyond puberty who rarely have had intercourse. The growth of the tubercle bacilli implies some local or general predisposition of the individual; one factor in this predisposition is evidently found in the conditions developed during the rapid growth of a part. Thus in childhood the epiphyses of long bones frequently afford a nidus for the growth of the parasite, while the rudimentary sexual organs are never affected primarily; but when with puberty the genital organs begin a rapid development, they are especially prone to become the site of the infection.

The tuberculous testicle should be excised, provided the prostate and seminal vesicles are apparently healthy, to remove the chances of further infection. While it is of course possible that there may be other and undiscovered foci of infection in various parts of the body—lymphatic glands, lungs or elsewhere—yet castration not only removes one, perhaps the only tuberculous nidus, but especially diminishes the danger of infection of the prostate and seminal vesicles—a necessarily fatal as well as agonizing affection; tuberculosis of the lungs is sometimes arrested by proper climatic and hygienic conditions; but tuberculosis of the prostate never, so far as we know, by either hygienic, medical or surgical means.

DR. MCARTHUR had little to say in regard to the differential diagnosis. In regard to scrotal tumors there was a point upon which he would like to have light, viz.: whether Dr. Fenger would have the Society believe that tubercular testis is always the result of general tuberculosis; that is, that the tubercular bacilli are brought in the blood to the point where the local inflammation occurs. He had privately asked Dr. Belfield if such were the case, what would be the advantage of an early removal? He had removed a testicle that happened to be a tubercular one. The man was 35 years of age, in apparently robust health, with no evidence of pulmonary or kidney affection. Dr. McArthur advised the removal of the testicle and performed the operation. On microscopic examination all the characteristics of tubercular testicle were found; within two months and a half the man died of acute tuberculosis.

DR. CHRISTIAN FENGER said that fifteen years ago nobody would have thought of extirpating a tuberculous testicle, because we knew that after the abscess has opened and discharged for a long time, such persons, if put under favorable circumstances, given cod-liver oil, sent to the seashore or country, will recover. So far as general tuberculosis resulting from a tuberculous testicle was concerned, only about 25 per cent. of the patients, he thought, would become subject to general tuberculosis. In cases where the miliary tubercles were limited to the testicle, and all other parts of the body not as yet invaded, extirpation should be performed. It is a legitimate operation now, but has only become so within the last five years. It of course has to be limited to cases where, so far as we can find out, the tubercle is local in the epididymis. If the tuberculosis has invaded the vas deferens, it is difficult to see what good extirpation of the testicle could do except as a mere local measure. Another point in tuberculosis of the testicle makes us desire if possible to eradicate the local tuberculosis and thereby perhaps prevent the tuberculosis affecting the bladder. The patients are subject to most terrible suffering for a year or two before death when they get tuberculosis of the bladder. He did not think tuberculosis could be called local here except if it could be transmitted by cohabitation with a woman having tubercles of the uterus, much in the same way as the microbes of gonorrhoea are transferred, and this mode of infection is not proved as yet. The tubercles in the epididymis must origi-

nate in the same way as local tuberculosis in the bones, by arresting and accumulation of tubercle bacilli already preëxisting in the general circulation. He did not think it possible that, in the strict sense of the word, any of these tubercles could be called local.

DR. G. C. PAOLI did not claim to be a specialist, but had seen many tumors of the testicles and scrotum. Tumors of the scrotum often arise in connection with diseases of the prostate glands, and with strictures. He had seen tumors of the testicle produced by affections of these organs. Another thing that gives trouble in practice is neuralgia of the testicles, which is very difficult to diagnose because the only symptom we have is the severe pain in the testicle. Another kind of tumor which has not been mentioned is schirrous, and it is often difficult of diagnosis. Many that have been diagnosed as schirrous have been nothing but chronic orchitis. He once saw a testicle extirpated in the belief that it was schirrous, but it proved to be a case of chronic inflammation of the testicle.

DR. J. L. GRAY read a paper on

THE TREATMENT OF EPILEPSY BY LIGATION OF THE VERTEBRAL ARTERIES,

first proposed by Dr. Brown, of Calcutta, in 1831. Vertebral arteries furnish blood supply of the medulla, pons, cerebellum and posterior third of cerebrum. Real seat of local disease in epilepsy supposed to be in the medulla, especially in the vaso-motor centres and regions related thereto, as convulsive centre described by Nothnagel. Is great irritability of these centres. Attacks of epilepsy due to reflex excitement of these centres. Ligature vertebral arteries and there will be less blood sent to these diseased and hypersensitive centres. Thus is lessened tendency to epileptic seizures. Also, as several branches of the sympathetic nerve must be necessarily ligated at the time the arteries are, this serves to lessen vaso-motor spasm in the medulla. Dr. Gray recommends tying the arteries between the atlas and axis. Operation been performed in Chicago seven times, with benefit in one case, temporary benefit in two, no benefit in two, fatal result in one, and result not known in remainder. Dr. Gray drew the following conclusions: 1. Ligation of vertebral arteries should take its place as a recognized procedure in cases of epilepsy in those cases where causes of attacks come from some region outside of brain. 2. The artery should be tied as high up as possible and the ligature should include all fibres of the sympathetic nerve accompanying the vessel. 3. When side of brain first invaded by the disease can be determined, the artery of that side should be ligated, and if the lesion be bilateral both vertebral arteries should be ligated. The operation should be done not as a substitute but as an aid to other forms of treatment for the cure or relief of epilepsy.

DR. D. R. BROWER in opening the discussion thanked Dr. Gray for his very able paper so full of interest and scientific importance, and said the case which he reported to the State Medical Society two years ago is now not quite so favorable. Indeed, the

child has practically relapsed into the same condition she was at the time of the operation. For two or three months the change for the better in the child's condition was very manifest. In that case the ligation was made at one side, the intention was to have both arteries ligated, but such symptoms of collapse came on that it was deemed unwise to pursue the operation further, and there being so little benefit, the parents refused to have another operation. He thought with Dr. Gray that enough is before us favorable to the operation to recommend it in cases where everything else fails, and he would be disposed to press the operation in those cases where there seems to be some special disorder of the circulation in the medulla. He thought the trouble about the treatment of epilepsy is that we have included under this name a great many diseases, he was sure there are a great many kinds of epilepsy, and he thought we do not know how to differentiate these different kinds, therefore our treatment must be to a great extent imperfect. There seem to be cases of epilepsy that are confined to the medulla. The history of some cases led him to suppose that the medulla is the seat of the disease, and in such cases it seems that the operation might prove a benefit. He did not believe that the circulation is reëstablished through the circle of Willis nearly so rapidly as Dr. Gray would have us believe. The circle of Willis is made up of minute arteries. In this particular case, there was a manifest and profound impression made upon the area of distribution of the vertebral artery for weeks, and he did not believe the collateral circulation was speedily established. He had no doubt that this operation will do good in some cases, just as any other profound impression will if made upon the nervous system; the cutting and destruction of the connections through the various plexuses is beneficial, so is any extensive counter irritation. A seton added to other treatment that was only partially successful sometimes caused a wonderfully better result to follow. He had a case under observation in which the removal of a cicatrix has resulted in wonderful improvement in the patient's condition, whether due to the extensive counter irritation produced by the operation or removal of cicatrix he did not know. He believed the operation justifiable in cases that resisted the ordinary treatment. He was an earnest advocate of the surgical treatment of epilepsy, the best results he had seen in this disease having followed the use of the surgeon's knife. Quite a number of cases had come under his observation in which the cause of the affection seemed to be in the ovarian region, and surgical interference was followed by better results than from treatment by medicine. He thought the treatment of epilepsy by pills and powders one of the most unsatisfactory things that can be undertaken, and the proportion of cases benefited by drugs exceedingly small.

DR. CHRISTIAN FENGER asked as to Alexander's operation, whether he ligated at once on both sides. The first time Dr. Fenger ligated an artery the question presented itself if it would not be dangerous to ligate them both at the same time. He ligated the arteries at Dr. Jewell's request and consequently did not take responsibility for ligating both at once.

That question of course presents itself, and is truly interesting to see that the double simultaneous ligation of the vertebral arteries has never given rise to local brain symptoms. On the other hand, when we ligate a common carotid in case of epilepsy, we always have in mind the danger which may exist of emolition, from local cerebral anemia, and possibly death in a certain number of cases. The operation on the vertebral arteries is far preferable to the ligation of the carotid, if it should prove that there is no danger by the ligation of the vessels both at one time. As to the manner of operating: Alexander operated down low before the artery enters the vertebral canal, but according to Dr. Jewell's view it is necessary to ligate the vertebral arteries high up. I looked over the books of surgery and found that the method of ligating between the occiput and the atlas, and between the latter and the epistropheus, had been done on the cadaver, but not on living subjects. The reason why the vertebral artery had been ligated in former times was either for aneurism or wounds. There are very few instances on record, and the wounds and aneurisms were very dangerous cases, and Fischer in the German surgery of Billroth and Lurcke, published in 1880, said that the ligation of the vertebral artery between the occiput and atlas and between the atlas and the axis is practically impossible. On the cadaver it can be done as well between the occiput and atlas as the atlas and axis, but the operation is much easier between the atlas and axis. To ligate between the occiput and the atlas I consider almost practically impossible on the living subject. The ligation between the atlas and the axis can be done; I know that Andrews ligated there, but the cases on record are few. There has not as yet been any injury to the artery, but if we should tear the artery so that we could not get hold of vessel enough to ligate above and below, we would have much the same condition as in a traumatic aneurism of the artery. Warren, of Boston, who wrote his *Memoirs of Surgery* twenty years ago, gives one case of wounded artery that got well by compression, by filling up the wound, but in most cases we know how little effective the plugging of an arterial wound is. Of thirty-four wounds of the vertebral artery only five recovered. Four of these were treated by plugging or local applications; in one only the ligation between occiput and atlas was performed by me in 1881, and the case published in *Gaillard's Journal*, July, 1882. Dr. Fenger was afraid when taking up the vertebral artery of the possibility of wounding it before it is ligated.

DR. C. W. PURDY asked Dr. Gray whether the operation was followed by diabetes, as would be expected from an operation of that kind. It was pointed out in 1849 by Claude Bernard, that traumatic injuries to this tract of the brain gives rise to diabetes in numerous instances, and since that time the course of the diabetic influence has been pretty satisfactorily mapped out. It is said to leave the brain by vaso-motor filaments with the vertebral arteries going as far as the third cervical ganglion, passing along with and surrounding the subclavian arteries, and reaching the upper and middle dorsal. A section of these nerves at any place until we reach

the upper dorsal ganglion causes diabetes. Strange to say, section of the splanchnics does not cause diabetes, but he would expect to find traumatic diabetes as a result of this operation. He thought that diabetes as a result of the operation would be only temporary.

DR. HAROLD N. MOYER thanked Dr. Gray for the manner in which he had presented the subject and especially for the indications which he laid down for the operation. Dr. Moyer had uniformly bad results from the treatment of epilepsy by any operative procedure. He had never recommended an operation for trephining that was followed by good results. He had once recommended the removal of the ovaries, and it was done, but was not followed by a good result. In one case coming under his observation a man was trephined three times; the first time it was followed by a cessation of the epilepsy for eighteen months; the second, for a year; the last, by no cessation. He had found medication quite as bad; he had tried the bromides according to Hammond's method, without good results. During the last two years he had treated about one hundred cases of epilepsy and in only one case had there been any real benefit. He thought he should recommend this operation, and hoped it might not be as serious as one would be led to suppose from the deep seat of the artery, and the extensive destruction of tissue that must be made to reach it.

DR. D. R. BROWER said that at the discussion which followed his paper at Springfield, a gentleman present announced that this operation was first performed in this country sixty years ago by an army surgeon, stationed in St. Louis, upon a negro man who was his servant. The man recovered, but the case was never published. If this is so, an American surgeon was the first to essay the operation.

DR. J. L. GRAY in closing the discussion said that he had not had an opportunity, except in one case, to examine the urine, and in that there was a slight quantity of sugar for about a week. From all the literature he was able to examine the first operation was performed in 1831 by Dr. Brown.

CHICAGO GYNÆCOLOGICAL SOCIETY.

*Forty-Seventh Regular Meeting, Friday Evening,
May 28, 1886.*

THE PRESIDENT, DANIEL T. NELSON, M.D., IN
THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

TAIT ON ABDOMINAL SECTION FOR PELVIC ABSCESS.

The Secretary, Dr. Edward Warren Sawyer, read the following letter from MR. LAWSON TAIT:

My Dear Dr. Nelson:—If not too late, I should like to take part in the discussion which was entered into at the Gynæcological Society of your city upon "Abdominal Section for Pelvic Abscess." My remarks, of course, are discursive and not very conclusive, because they are based upon only a very few points to which I want to draw attention.

The first is this: I object to the use of words ending in *otomy*, to mean various operations all of which are practically identical in character but different in detail, and not one of which can have any exclusive or absolute identification by any particular name. Thus Professor Christian Fenger, in the discussion, objects to the word laparotomy, and he introduces another which is perfectly new to me, and I hope it will never be used again: it is *oncotomy*. Dr. Fenger objects to laparotomy in a sense where I certainly have no objections, and his very objections only show how utterly absurd all these words are. There really ought not to be any such word as laparotomy in existence, because the signification of its derivatives in the use of the people who spoke the language is such that it could not by any human ingenuity be applied to any modern surgical proceeding. Now the words "abdominal section" are sufficiently English to be understood by everybody, and they are sufficiently distinctive to enable us to understand at once that when they are used the peritoneum is opened. I therefore wish through your powerful society to protest against the use of all these stupid words of Greek formation. I wish also to protest against the absurd distinctions drawn by Sanger which are quoted by Dr. Fenger on the subject of pelvic abscess.

He distinguishes six kinds of salpingitis.

1. *Septic*, the existence of which I entirely dispute as a specific ailment.
2. *Tuberculous*, which again I deny except that it has an existence as the third and contracting stage of pyosalpinx.
3. *Syphilitic*, not one particle of evidence of this have I ever seen.
4. *Actino-Mycotic*, which is an equally ridiculous subdivision, based on mere theory, not on fact.
5. *Gonorrhæal*, to which a great bulk of the cases belong.
6. *A mixed form*. Instead of this sixth or mixed form, I would say that there are a great many cases to which we cannot attribute any actual origin, a number of cases occurring in virgins where the existence of gonorrhœa would be an impossibility, and where there was no puerperal mischief.

Dr. Fenger's paper has always seemed to me to be an illustration of the German savant evolving the descriptions of the camel out of his own consciousness. My descriptions, on the other hand, are taken from some hundreds of cases upon which I have performed operations and the history of which I know as completely as it is possible to obtain information.

In Dr. Reeves Jackson's paper there are two points to which I want specially to draw attention, and they are not of much importance because they are chiefly questions personal to myself.

The first is a passage in which it is said: "Lawson Tait, of Birmingham, and Martin, of Berlin, were the first who attempted to prevent the terrible contingencies of pelvic inflammations by attacking the disease at its original seat. Lawson Tait removed the suppurating uterine appendages, Martin operated for suppurating periuterine hæmatocele. Tait operated for a suppurating hæmatoma of the right Fal-

lopian tube in 1878, and he removed both tubes for pyosalpinx, and an ovary for abscess in 1885. In 1885 Martin performed laparotomy in three cases of intraperitoneal hæmatoma, namely, retrouterine hæmatocele." Now accuracy of date in a matter of this kind is rather important for one's own personal reputation, and Professor Reeves Jackson has underestimated my claim for priority by at least seven years. The first operation which I performed for suppuration of the uterine appendages was done on the 11th of February, 1872, and there will be found in the last edition of my book on "Diseases of the Ovaries," twenty-two cases which I had performed up to the middle of August, 1882, without a death. Since then I have operated upon hundreds. The first case of suppurating hæmatocele which I operated upon is published in detail in the same book; it was in February, 1879, and since then I have operated upon thirty-two cases without a death, and all have been completely cured. It will thus be seen that in none of these matters have the German surgeons approached English surgery as rivals in priority. They have been mere followers in every particular, and I regret to say their following has been practiced without that recognition to which our priority gives us every just claim.

The second point is that in which I find Professor Byford speaking in terms of my own work which no words of mine can sufficiently recognize or express my appreciation of, and here certainly his words of caution are worthy of a little note. What I fear, in fact what I already feel, is that the remarkable success which I have had, and of which Professor Byford speaks in such strong terms, is really leading astray those whose opportunities have not been as my own, into the belief that the work is easy, simple, easily acquired and free from risk. It is not so, and unless those who practice it choose to follow me in the rigid precautions and immense care which I give, not only to the mere performance of the operation, but to the surroundings of my patients and to every detail in connection with them, they will not obtain, they must not expect, the success which I have had. I have said that I fear, in fact, I already feel, that this success of mine is leading people astray, and I want to urge in the name of humanity, as well as for the sake of the art we practice, that there should be less of the indiscriminate rushing into this kind of work which has already been deplored on both sides of the Atlantic. I am, etc.,

LAWSON TAIT.

7, The Crescent, Birmingham, April 14, 1886.

DR. A. REEVES JACKSON said: We ought, I am sure, to feel honored by having among us in spirit, if not in person, so eminent a man as the writer of this letter. Lawson Tait is in some respects the greatest living surgeon, a Gamaliel at whose feet we all find ourselves sitting; and, withal, a man so observant that not a single gynæcological sparrow falls in any part of the world unnoticed by him. I must plead "not guilty" to the charge—made against me by Mr. Tait—of inaccuracy regarding the date of his first laparotomy for pelvic abscess—the remarks upon this point having been made by another, and not by me. As stated in the letter, his first operation of

this nature was done February 11, 1872, at Birmingham, on a patient of Mr. Hallwright. I am sure that Mr. Tait will not for a moment suppose that any of us would willingly do injustice to one whom we all esteem so highly, and from whom many of us have been recipients of acts of kindness and courtesy.

In regard to the justice of Mr. Tait's criticism on the prevalent use of the words ending in "otomy" I do not feel like being an arbiter. Technical words are frequently necessary, and yet, as a general rule, I think it preferable to use simple language. The ordinary English words are commonly sufficient to answer all the purposes of language. Besides, large and unusual words are sometimes embarrassing. When, some weeks ago, Professor Fenger charged me with performing an "oncotomy" I was afraid that I had done something very dreadful, and the worse because I did it without knowing it. I felt very much as the fisherwoman did, when Daniel O'Connell in response to her volley of ordinary, undecorated profanity called her a parallelogram. The fisherwoman did not know what to say, and I could not reply; we both had evidently lost the thread of the discussion. I am glad that Mr. Tait speaks so strongly in regard to the tendency now so frequently indulged in, to perform laparotomies, and that he is willing to correct to some extent by his words the mischief that has been done by his powerful and successful work. It seems that when some persons visit Mr. Tait and witness his success and simple but effective methods, they come back thinking life is a blank unless they can own and manage an abdominal hospital and spend the remainder of their days in the cheerful occupation of removing uteri and ovaries.

DR. CHRISTIAN FENGER said: The letter which Mr. Lawson Tait wrote to Dr. Nelson relates in a number of points to my paper on "Laparotomy for Periuterine Abscess," as well as to some remarks which I made before the Society in a previous discussion. I must, therefore, beg the Fellows of the Society to bear with me if I take up a little of their time in answering Mr. Tait's letter.

Discussing Professor A. Reeves Jackson's paper, I objected to calling the operation in question a laparotomy. According to the Professor's description of the case, he had opened an abscess which was adherent to the anterior abdominal wall. He had consequently simply performed an oncotomy, an operation which, notwithstanding the division of the abdominal wall, does not differ materially from opening a deep-seated abscess in any other region of the body, as *ex. gr.* in an extremity.

Whether opening the abdominal or peritoneal cavity be termed laparotomy or abdominal section or *Bauch-Schnitt*, is of course a matter of indifference, provided only that the meaning of the word be agreed upon. There is but one way of getting at the signification of a medical term, and that is by learning in what sense the term is employed in the medical literature of the different nations.

I must again maintain that laparotomy is not merely section of the abdominal parietes, but that the word implies opening of the general peritoneal cavity with a view to perform some operation within

that cavity. (*See Linhardt's Operationslehre*. Wien 1862, p. 705 and *Eulenburg, Realencyclopädie*, Bd. II, p. 37.) French authors occasionally use the word gastrotomy instead of laparotomy. Recently the operation has been called peritonotomy, which on account of its correctness should perhaps be preferred to the other terms.

It is of importance to distinguish between a laparotomy and the evacuation of a limited abscess by simply incising the abdominal wall. The two operations differ widely as to their consequent dangers. Where the general peritoneal cavity is opened, a well-known series of precautionary measures is required before and during the operation, in order to protect the patient from general septic peritonitis.

Where an incision through the abdominal parietes leads directly into a limited abscess-cavity, the precautionary measures essential to laparotomy may be dispensed with; the general peritoneal cavity is not opened and there is no fear of general peritonitis. In the latter operation the peritoneum is not seen or not taken notice of, the incision wound is left open and the limited cavity washed out and drained.

In every country medical authors hold these two operations apart. Opening a perityphlitic abscess, an adherent hepatic abscess or a parametric abscess above Poupart's ligament is never spoken of as a laparotomy. Whenever we hear or read of a man having performed a series of laparotomies we naturally suppose that he is experienced in performing intraperitoneal operations. Now, many a surgeon has opened a large number of intraabdominal abscesses and has never seen the peritoneal cavity.

It is evidently important properly to limit the meaning of the term laparotomy; else we may misunderstand the description of a given case, and the statistics of laparotomies will necessarily be rendered valueless.

The next point Mr. Lawson Tait remarks upon is the question of priority of operating for pelvic hæmatocele. By the mistake of Mr. Tait, part of what I said in the discussion of Professor Jackson's paper is ascribed to the paper itself. I am thus quoted in his letter:

"Lawson Tait, of Birmingham, and Martin, of Berlin, were the first who attempted to prevent the terrible consequences of pelvic inflammations by attacking the disease at its original seat. Lawson Tait removed the suppurating uterine appendices; Martin operated for suppurating periuterine hæmatocele."

In the discussion I stated the dates at which Tait and Martin performed their respective operations. By a typographical error the dates appeared wrong in some of the copies of the transactions of the Society. 1885 instead of 1872 was given as the date of Tait's first laparotomy for abscess of the ovary, and 1885 instead of 1876 as that of Martin's first laparotomy for extraperitoneal hæmatocele.

Considering my remarks as a whole and examining my references to the literature on the subject a careful reader would not have failed to recognize in the wrongly printed dates a typographical error.

Lawson Tait performed his first laparotomy for

extraperitoneal hæmatocele in February 1879. (See Lawson Tait: *Diseases of the Ovaries*. 4th Edition. London 1883, p. 346, and Tait's letter.)

Martin performed the same operation for the first time in 1877, and a second time on the 31st of January, 1879. (See A. Martin: *Das extraperitoneale periuterine Hæmatom*. *Zeitschrift für Geburtshülfe und Gynekologie*. VIII Bd. Hft. II, 1882, p. 476.)

It will thus be seen that my statements concerning priority were correct. In the discussion of Professor Jackson's paper I quoted Säger's classification of pelvic inflammations. In criticising it, Mr. Lawson Tait speaks of "absurd distinctions." I wish to repeat that I regard Säger's classification as complete and correct and in accordance with the laws governing inflammatory processes in all organs of the body.

To Mr. Lawson Tait's manner of criticising my little paper "On Chronic Periuterine Abscess and its Treatment by Laparotomy," which appeared in the May number of the *Annals of Surgery*, 1885, there is but one answer. Like all published articles it is open to criticism. If anybody should wish to attack it, I am ready to enter into a discussion of it, provided that tangible objections to it be brought forward.

(To be concluded.)

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS
TO BE HELD IN WASHINGTON, D.C.,
COMMENCING SEPT. 5, 1887.

CIRCULAR NO. 2.

The Ninth International Medical Congress will assemble in the City of Washington, the Capital of the United States, on Monday, September 5, 1887, at 12 o'clock noon, in accordance with the arrangements made at Copenhagen in August, 1884.

Patrons.—The President of the United States, the Hon. Grover Cleveland; the Secretary of State, the Hon. Thomas F. Bayard; the President of the Senate of the United States, the Hon. John Sherman; the Speaker of the House of Representatives of the United States, the Hon. John G. Carlisle.

PROPOSED OFFICERS OF THE CONGRESS.

President.—Nathan S. Davis, M.D., LL.D., Professor of the Principles and Practice of Medicine and of Clinical Medicine, Chicago Medical College, and of Mercy Hospital, Chicago, Illinois.

Vice-Presidents, as far as appointed.—McCall Anderson, M.D., London, England; Mr. Thomas Annandale, Professor of Clinical Surgery, Edinburgh University, Edinburgh, Scotland; Professor Dujardin-Beaumetz, M.D., Paris, France; Cuthbert Hilton Golding-Bird, M.D., Professor of Physiology, Guy's Hospital, London, England; Professor Carl Braun, M.D., Vienna, Austria; William Brodie, M.D., Emeritus Professor of Principles and Practice of Medicine and Clinical Medicine, Detroit College of Medicine, Detroit, Michigan; W. W. Dawson, M.D., Professor of Surgery and Clinical Surgery, Medical College of

Ohio, Cincinnati, Ohio; Thomas M. Dolan, M.D., Halifax, England; F. R. Frazer, M.D., Professor of Materia Medica and Therapeutics, University of Edinburgh, Edinburgh, Scotland; J. A. Grant, M.D., Ottawa, Canada; J. A. S. Grant, M.D., Cairo, Egypt; A. L. S. Gusserow, M.D., Professor of Obstetrics, Berlin, Prussia; Dr. Hans Ritter von Hebra, Vienna, Austria; Dr. E. Klein, London, England; M. Le Baron H. Larrey, Paris, France; Sir William MacCormac, Surgeon St. Thomas's Hospital, London, England; Mr. George B. MacLeod, Professor of Surgery, Glasgow, Scotland; John S. McGrew, M.D., Honolulu, Hawaiian Islands; E. M. Moore, LL.D., Rochester, New York; Professor von Monseil, Bonn, Prussia; Dr. Müller, Berlin, Prussia; William Murrell, M.D., London, England; Charles D. F. Phillips, M.D., M.R.C.S., late lecturer on Materia Medica and Therapeutics, Westminster Hospital, London, England; Richard Quain, M.D., Professor of Anatomy, London, England; Tobias G. Richardson, M.D., Professor of General and Clinical Surgery, Medical Department Tulane University, New Orleans, Louisiana; M. P. Ricord, Paris, France; Professor John Burdon-Sanderson, M.D., London, England; Lewis A. Sayre, M.D., Professor of Orthopædic and Clinical Surgery, Bellevue Hospital Medical College, New York; Dr. Mariano Semmola, Professor of Experimental Therapeutics, University of Naples, Italy; Dr. Leopold Servais, Antwerp, Belgium; J. M. Toner, M.D., Washington, D.C.; Dr. P. G. Unna, Hamburg, Germany; Professor F. Winckel, Dresden, Saxony; the President of the American Medical Association; the Surgeon-General of the United States Army; the Surgeon-General of the United States Navy;

Secretary-General.—John B. Hamilton, M.D., Supervising Surgeon-General of the United States Marine Hospital Service; Professor of Surgery, Georgetown University, D. C.; Professor of Surgery, Chicago Polyclinic.

Treasurer.—E. S. F. Arnold, M.D., M.R.C.S., Newport, Rhode Island.

Chairman of the Finance Committee.—Richard J. Dunglison, M.D., Philadelphia, Pennsylvania.

Chairman of the Executive Committee.—Henry H. Smith, M.D., LL.D., Emeritus Professor of Surgery in the University of Pennsylvania, Philadelphia, Pennsylvania.

Chairman of the Committee of Arrangements.—A. Y. P. Garnett, M.D., Emeritus Professor of Clinical Medicine, Columbia University, Washington, D. C.

Associate Secretaries of the Congress.—William B. Atkinson, M.D., Philadelphia, Pennsylvania; G. B. Harrison, M.D., Washington, D. C.

The Congress will consist of such members of the Regular Medical Profession as shall have registered and taken out their ticket of admission, and of such other Scientific men as the Executive Committee of the Congress shall deem it desirable to admit. The books for the Registration of Members will be open from 9 A.M. to 5 P.M. on Thursday, September 1, 1887, and on each subsequent day during the Session, under the charge of the "Reception Committee." Any member desiring to anticipate this Registration, can apply by letter to the Secretary-General and forward

his dues, with his address in full, when a receipt will be returned.

The dues of Membership for residents of the United States will be Ten dollars (\$10). There will be no dues for members residing in other countries. Each member will be entitled to receive a copy of the "*Transactions*" of the Congress, when published by the Executive Committee.

The General Sessions of the Congress will be devoted to the transaction of business and Addresses and communications of general scientific interest, by members appointed by the Executive Committee. A printed "Programme" of the Sessions will be presented to each member on registering. A printed "Order of Business" for each day will also be issued.

The work of the various Sections will be directed by the President of the Section, and the order will be published in a daily Programme for each Section. Questions and topics that have been agreed on for discussion in the Sections shall be introduced by members previously designated by the titular officers of each Section. Members who have been appointed to open discussions shall present to the Secretaries of the Section, in advance, statements of the conclusions which they have formed as a basis for the debate.

Brief abstracts of Papers to be read in the Sections shall be forwarded to the Secretaries of the proper Section on or before *April 30, 1887*. These abstracts shall be treated as confidential communications, and shall not be published before the meeting of the Congress. Papers relating to topics not included in the list of subjects proposed by the Officers of the Sections, may be accepted after April 30, 1887, and any member wishing to introduce a topic not on the regular list of subjects for discussion, shall give notice of the same to the Secretary General at least twenty-one days before the opening of the Congress. The titular officers of each Section shall decide as to the acceptance of such proposed communications, and the time for their presentation. No communications shall be received which has been already published or read before a Society.

The official languages of the Congress shall be English, French and German. Each paper or address shall be printed in the "*Transactions*" in the language in which it was presented. Preliminary abstracts of papers and addresses shall also be printed in the language in which each is to be delivered. All discussions shall be printed in English.

The officers of the Congress and the officers of the Sections, including all Foreign officers, will be nominated to the Congress by the Executive Committee, at the opening of the first Session. A partial list of the officers to be nominated (except the members of Council of the different Sections, the list of whom is at present imperfect), is offered herewith.

The Executive Committee cordially invites members of the regular medical profession, and men eminent in the sciences collateral to medicine, in all countries, to participate, in person or by papers, in the work of this great humanitarian assembly. Communications relating to appointments for papers to be read in the Congress should be addressed to Dr.

John B. Hamilton, Secretary-General of the Ninth International Medical Congress, Washington, District of Columbia. All questions or communications connected with the business of the Executive Committee should be addressed to Dr. Henry H. Smith, Chairman of the Executive Committee of the Ninth International Medical Congress, Philadelphia, Pennsylvania. Gentlemen named in any position in the Congress are requested to notify the Chairman of the Executive Committee, as soon as practicable, of any error in the name, title or address in this circular.

Ladies in attendance with members of the Congress, and those invited by the "Reception Committee," may attend the General Sessions of the Congress when introduced by a member. They will also be invited to attend the Social Receptions. The Executive Committee reserves the right to invite distinguished persons to any or all the meetings of the Congress. The attendance of Medical Students and others interested in the work of the various Sections or in the general addresses delivered in the Congress, will be permitted, on the recommendation of the Secretary-General or the officers of a Section, on their taking out from the Registration Committee a general ticket of admission, fee one dollar (\$1); but such persons cannot take part in the proceedings.

All communications and questions relating to the special business of any Section, must be addressed to the President or one of the Secretaries of that Section. As many details of the Congress and numerous appointments of officers are yet to be completed, other Circulars will be issued from time to time, as circumstances may demand.

The following is the list, as at present completed:

EXECUTIVE COMMITTEE OF THE CONGRESS.

Henry M. Smith, M.D., LL.D., *Chairman*; N. S. Davis, M.D., LL.D.; John B. Hamilton, M.D.; E. S. F. Arnold, M.D.; Richard J. Dunglison, M.D., *Secretary*; Abram B. Arnold, M.D.; William T. Briggs, M.D.; De Laskie Miller, M.D., Ph.D.; James F. Harrison, M.D.; F. H. Terrill, M.D.; William H. Pancoast, M.D.; John H. Callender, M.D.; Alonzo B. Palmer, M.D., LL.D.; J. Lewis Smith, M.D.; E. Williams, M.D.; S. J. Jones, M.D., LL.D.; William H. Daly, M.D.; A. R. Robinson, M.D.; Joseph Jones, M.D.; Albert L. Gihon, M.D.; John P. Gray, M.D., LL.D.; Jonathan Taft, M.D.; Frederick S. Dennis, M.D.; A. Y. P. Garnett, M.D.

PRESIDENTS OF SECTIONS.

General Medicine.—Abram B. Arnold, M.D., Professor of Clinical Medicine, College of Physicians and Surgeons, Baltimore, Md.

General Surgery.—William T. Briggs, M.D., Professor of Surgery, University of Nashville, Nashville, Tenn.

Military and Naval Surgery and Medicine.—Henry H. Smith, M.D., LL.D., Emeritus Professor of Surgery, University of Pennsylvania, and formerly Surgeon-General of Pennsylvania, Philadelphia, Pa.

Obstetrics.—DeLaskie Miller, M.D., Ph.D., Professor of Obstetrics, Rush Medical College, Chicago, Ill.

Gynecology.—James F. Harrison, M.D., Professor of Obstetrics, etc., University of Virginia, Va.

Therapeutics and Materia Medica.—F. H. Terrill, M.D., Professor of Therapeutics, University of California, San Francisco, Cal.

Anatomy.—William H. Pancoast, M.D., Professor of General, Descriptive and Surgical Anatomy, Medico-Chirurgical College, Philadelphia, Pa.

Physiology.—John H. Callender, M.D., Professor of Physiology and Psychology, University of Nashville, Nashville, Tenn.

Pathology.—Alonzo B. Palmer, M.D., LL. D., Professor of Pathology, University of Michigan, Ann Arbor, Mich.

Diseases of Children.—J. Lewis Smith, M.D., Professor of the Diseases of Children, Bellevue Hospital Medical College, New York, N. Y.

Ophthalmology.—E. Williams, M.D., Professor of Ophthalmology, Miami Medical College, Cincinnati, Ohio.

Otology.—S. J. Jones, M.D., LL.D., Professor of Ophthalmology and Otology, Chicago Medical College, Chicago, Ill.

Laryngology.—William H. Daly, M.D., Pittsburg, Pa.

Dermatology and Syphilis.—A. R. Robinson, M.D., Professor of Dermatology, New York Polyclinic, and of Histology and Pathological Anatomy, Woman's Medical College of the New York Infirmary, New York, N. Y.

Public and International Hygiene.—Joseph Jones, M.D., Professor of Chemistry and Clinical Medicine, Tulane University; Ex-President Board of Health, New Orleans, La.

Medical Climatology and Demography.—Albert L. Gihon, M.D., Medical Director, U. S. Navy.

Psychological Medicine and Nervous Diseases.—John P. Gray, M.D., LL.D., Professor of Psychological Medicine and Medical Jurisprudence, Bellevue Hospital Medical College, Utica, N. Y.

Dental and Oral Surgery.—Jonathan Taft, M.D., Professor of Dental and Oral Surgery, University of Michigan, Ann Arbor, Mich., Cincinnati, Ohio.

VICE-PRESIDENTS OF SECTIONS.

General Medicine.—W. W. Cleaver, M.D., Kentucky; J. A. Oeternoney, M.D., Kentucky; P. G. Robinson, M.D., Missouri; Thos. F. Rochester, M.D., New York; Preston B. Scott, M.D., Kentucky.

General Surgery.—Professor Filanus, Holland; Moses Gunn, M.D., Illinois; J. W. Hamilton, M.D., Ohio; W. H. Hingston, M.D., Canada; James M. Holloway, M.D., Kentucky; J. C. Hutchison, M.D., New York; N. S. Lincoln, M.D., District of Columbia; Donald MacLean, M.D., Michigan; Donald Macrea, M.D., Iowa; M. Storrs, M.D., Connecticut.

Military and Naval Surgery and Medicine.—C. J. Cleborne, M.D., United States Navy; E. H. Gregory, M.D., Missouri; Frank H. Hamilton, M.D., New York; W. T. Hord, M.D., United States Navy; Frederick Hyde, M.D., New York; G. I. Porter, M.D., Connecticut; Wm. E. Taylor, M.D.,

United States Navy; Edward Warren-Bey, M.D., France; B. A. Watson, M.D., New Jersey.

Obstetrics.—Gustav Braun, M.D., Austria; P. Budin, M.D., France; J. Galabin, M.D., England; John Goodman, M.D., Kentucky; W. M. Knapp, M.D., Nebraska; R. Lowry Sibbet, M.D., Pennsylvania; Isaac E. Taylor, M.D., New York.

Gynecology.—N. Bozeman, M.D., New York; Henry O. Marcy, M.D., Massachusetts; T. A. Reamy, M.D., Ohio; R. R. Storer, M.D., Rhode Island.

Therapeutics and Materia Medica.—Henry M. Field, M.D., New Hampshire; Albert Frické, M.D., Pennsylvania; George Gray, M.D., Ireland.

Anatomy.—C. W. Kelly, M.D., Kentucky; Samuel Logan, M.D., Louisiana.

Physiology.—

Pathology.—Andrew Fleming, M.D., Pennsylvania; J. B. Johnson, M.D., Missouri; Henry F. Lyster, M.D., Mich.

Diseases of Children.—William B. Atkinson, M.D., Pennsylvania; William G. Booker, M.D., Maryland; William H. Day, M.D., England; Dr. Cadet de Gassicourt, France; Dr. J. Grancher, France; Dr. Edward Henoch, Prussia; Adoniram B. Judson, M.D., New York; J. P. Oliver, M.D., Massachusetts; Eustace Smith, M.D., England; Charles West, M.D., England; Joseph E. Winters, M.D., New York.

Ophthalmology.—A. W. Calhoun, M.D., Georgia; J. J. Chisholm, M.D., Maryland; P. D. Keyser, M.D., Pennsylvania; Dudley S. Reynolds, M.D., Ky.

Otology.—

Laryngology.—M. F. Coomes, M.D., Kentucky; J. H. Hartman, M.D., Maryland; J. O. Roe, M.D., New York; E. L. Shurley, M.D., Michigan; G. V. Woolen, M.D., Indiana.

Dermatology and Syphilis.—James M. Keller, M.D., Arkansas; John V. Shoemaker, M.D., Pennsylvania; George Thin, M.D., London, England.

Public and International Hygiene.—A. Nelson Bell, M.D., New York; John Berrien Lindsley, M.D., Tennessee; J. N. McCormack, M.D., Kentucky; J. F. Y. Paine, M.D., Galveston, Texas; Benjamin W. Richardson, M.D., England; John Simon, M.D., England; J. W. Thudicum, M.D., England.

Medical Climatology and Demography.—Dr. A. Chervin, Paris, France; Traill Green, M.D., Pennsylvania; John H. Hollister, M.D., Illinois.

Psychological Medicine.—Julius Althaus, M.D., England; R. H. Chase, M.D., Pennsylvania; Eugene Grissom, M.D., North Carolina; John C. Hall, M.D., Pennsylvania; P. A. Hooper, M.D., Arkansas; J. S. Jewell, M.D., Illinois; S. S. Schultz, M.D., Pennsylvania.

Dental and Oral Surgery.—W. W. Allport, M.D., Illinois; S. W. Dennis, M.D., California; C. L. Ford, M.D., Michigan; H. L. McKellops, M.D., Missouri; A. T. Metcalf, M.D., Michigan; W. H. Morgan, M.D., Tennessee; A. L. Northrop, M.D., New York; L. D. Shepard, M.D., Massachusetts.

SECRETARIES.

General Medicine.—J. W. Chambers, M.D., Baltimore, Maryland.

General Surgery.—Dudley P. Allen, M.D., Cleveland, Ohio; Carl Mayde, M.D., Germany; J. R. Weist, M.D., Richmond, Ind.; A. H. Wilson, M.D., South Boston, Mass.

Military and Naval Surgery and Medicine.—J. McF. Gaston, M.D., Atlanta, Georgia; E. A. Wood, M.D., Pittsburg, Pa.

Obstetrics.—A. Charpentier, M.D., Paris, France; T. Felsenreich, M.D., Vienna, Austria; W. W. Jagard, M.D., Chicago Ill.; John Williams, M.D., London, Enland.

Gynecology.—Earnest W. Cushing, M.D., Boston, Mass.

Therapeutics.—Frank Woodbury, M.D., Philadelphia, Pa.

Anatomy.—Henry Morris, M.D., Philadelphia, Pa.

Physiology.—R. W. Bishop, M.D., Chicago, Ill.

Pathology.—H. M. Biggs, M.D., New York, N. Y.; I. N. Himes, M.D., Cleveland, Ohio.

Diseases of Children.—Dillon Brown, M.D., New York.

Ophthalmology.—S. C. Ayres, M.D., Cincinnati, Ohio.

Otology.—S. O. Richey, M.D., Washington, D. C.

Laryngology.—William Porter, M.D., St. Louis, Missouri.

Dermatology.—W. T. Corlett, M.D., Cleveland, Ohio; F. E. Daniel, M.D., Austin, Tex.

Public and International Hygiene.—George H. Rohé, M.D., Baltimore, Md.; Walter Wyman, M.D., U. S. Marine Hospital Service, New York, N. Y.

Climatology and Demography.—Charles Denison, M.D., Denver, Colorado; James F. Todd, M.D., Chicago, Illinois.

Psychological Medicine.—E. D. Ferguson, M.D., Troy, N. Y.; E. Landolt, M.D., (Berlin, Prussia), Paris, France.

Dental and Oral Surgery.—Edward A. Bogue, M.D., New York, N. Y.; S. F. Rehwinkle, M.D., Chillicothe, Ohio.

COMMITTEE OF ARRANGEMENTS, WASHINGTON, D. C.

A. Y. P. Garnett, M.D., Chairman; J. M. Toner, M.D., Vice-Chairman; C. H. A. Kleinschmidt, M.D., Secretary; D. C. Patterson, M.D., Treasurer.

Executive Committee.—Drs. A. Y. P. Garnett, J. M. Toner, N. S. Lincoln, C. H. A. Kleinschmidt, Surgeon-General F. M. Gunnell, M.D., U. S. Navy; Surgeon-General Robert Murray, M.D., U. S. Army; Supervising Surgeon-General J. B. Hamilton, M.D., U. S. Marine Hospital Service; Chief Medical Purveyor J. H. Baxter, M.D., U. S. Army.

Committee on Congressional Legislation.—Dr. A. Y. P. Garnett, Chairman.

Committee on Finance.—Dr. G. L. Magruder, Chairman.

Committee on Printing.—Dr. J. B. Hamilton, Chairman.

Committee on Reception.—Dr. J. M. Toner, Chairman.

Committee on Entertainments.—Dr. N. S. Lincoln, Chairman.

Committee on Transportation.—Dr. J. W. H. Lovejoy, Chairman.

Committee on Place of Meeting for Congress and Sections—Dr. D. C. Patterson, Chairman.

By order of the Executive Committee of the Congress.

HENRY H. SMITH, M.D., Chairman.

RICHARD J. DUNGLISON, M.D., Secretary.

[Our exchanges are earnestly requested to copy this circular.]

TO THE PRESIDENT OF THE CONGRESS:

Dear Sir:—In accordance with the request of Dr. Joseph Jones, of New Orleans, La., President of the XIVth Section of the Ninth International Medical Congress, I will investigate the important questions embraced under Section VI of the Inquiries prepared for the Council of this Section by Dr. Jones. In order to throw light upon these important questions, I have upon consultation with the President of the XIVth Section, drawn up the following questions, relating chiefly to the effects of overflows and rice-culture upon the Public Health; and in order to obtain reliable information I address the following interrogations to the medical men in those localities, and respectfully request, as early as possible, a full and specific answer to each question.

Question 1. How long have you been cognizant of the results of overflows of the Mississippi river and its tributaries upon the Public Health?

2. Have you closely observed the effects of said overflows upon the Public Health?

3. Have you generally or uniformly observed an increase of sickness immediately succeeding these overflows?

4. If so, what diseases? Their character and type?

5. What local or general conditions (including topography) have you noted, controlling or modifying the effects of overflows upon the Public Health?

6. Have you kept statistics of the number and dates of these overflows, and the cases of sickness (if any) resulting therefrom? If so please give these statistics.

7. What is your experience of the effects of rice-culture upon the Public Health? and what the rate of death per 1000 population before and since the commencement of rice-culture?

8. Has malarial hæmaturia increased in frequency and severity during the past forty years? And is said increase due to the increased cultivation of rice in the Delta of the Mississippi river, or in other localities where rice is cultivated?

9. What effect has the camping and working of State prisoners in the low lands and swamps had upon said prisoners, held by Louisiana, Arkansas, Mississippi or other States so employing their prisoners.

10. How many deaths have been caused among State prisoners by malarial diseases, directly traceable to exposure to the malaria of the swamps?

11. Give facts bearing upon the relative effects of overflows and rice-culture upon the colored and white races?

12. Relations of drinking water to the health of the inhabitants of rice, sugar, and cotton plantations? Effects of swamp water? effects of cistern, well and spring water, for drinking purposes?

13. The best means of protecting the health of the laborers and inhabitants in such localities?

The physicians of the valley of the Mississippi river and the rice regions of Arkansas, of Alabama, Georgia, North and South Carolina, Florida and Texas, are earnestly requested to furnish their replies to

RICHARD H. DAY, M.D.,
Baton Rouge, La. P. O. Box 181.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

THE INTERNATIONAL MEDICAL CONGRESS.—Our latest information is to the effect that the arrangements for the great International Congress at Washington are progressing favorably. In the case of many of our European brethren the occasion of a visit to the United States will be a unique one in their lives. We have not yet reached that familiarity with the Atlantic which is such an attainment in our American brothers:

Qui siccis oculis monstra natantia,
Qui vidit mare turgidum.

Nevertheless, many on this side are anxious to return the visits so generously made from the other. And whatever the discomforts of the voyage or the severity of the *mal de mer*, we are likely to have the advantage of much brotherly assistance and advice. It may mark a new era in the treatment of sea-sickness, when so many zealous physicians and surgeons are set in competition for their own relief. Be this as it may, great preparations are being made in Washington and elsewhere, and it only remains for Europe to see that the guests are forthcoming. It is the great element in all such gatherings that they be well "furnished with guests," and we would now urge on the profession and its leaders that they will do a great service by an early decision to attend, and still more by an early intimation of it to those concerned. There are American physicians who have visited England annually for thirty or forty years, and on rare occasions perhaps more than once in the year. The late Dr. Flint, whose absence will be

acutely felt at Brighton this year and at Washington next, had come of late years to think nothing so refreshing as a run to the old home of his forefathers. Let us reciprocate the compliment on this high occasion, and make the very Atlantic the measure of our desire to cultivate international science and friendship—*Lancet*, July 24, 1886.

GLANDERS IN MAN has been heretofore considered a wellnigh incurable disease. The *Sanitary News* states that Dr. C. N. Cooper, county physician of Kane county, Ill., reports the recovery of a case which has been of two years' duration. A man died from the disease near Elgin and his wife contracted the disease from him. She has, after much suffering, so far recovered as to be able to support herself.

TYROTOXICON IN ICE-CREAM.—Prof. Victor C. Vaughan has discovered tyrotoxin, or cheese poison, in some ice-cream which recently caused serious trouble in Michigan. The poison has thus been found in cheese, curd, and in ice-cream.

PROFESSOR KAPOSÍ will take the editorship of the *Archiv für Dermatologie und Syphilis*, made vacant by the death of Prof. Auspitz. Prof. Pick, of Prague, will remain co-editor.

CAN A MAN HAVE A FEMALE COMPLAINT?—A young man entered the Dispensary of the Chicago Polyclinic recently, and going up to the clerk held out one of the Dispensary circulars with the question: "Say! isn't this the hour for diseases of women?" The clerk answered in the affirmative, when the young man said: "Well! I've got a disease of a woman and want to be treated."

CAVOUR AND BISMARCK ON STATE MEDICINE.—A little volume of some seven hundred pages, entitled "La Sapienza Politica del Cavour e del Bismarck," has just appeared, says *The Lancet*, under the competent editorship of SIGNOR FILIPPO MARIOTTI, the well-known Italian publicist and man of letters. Though primarily designed for the student of politics, the book has a great deal to interest the professional man, and not least the votary of the healing art, dealing as it does with the relations of hygiene to the State, with the right of Government to interfere in professional education, in the food and water supply of the community, and in the complex social questions which are brought home to the busy practitioner every day of his life. Signor Mariotti, remembering the saying of Bossuet, "C'est la maxime qui fait les grands homes," has perused the many discourses of the great Italian and German statesmen with a vigilant eye to those passages in which years of special thought and experience are condensed and crystallized, so to speak, in pregnant apophthegms and memorable sayings; and the result is a volume of inductions and illustrations which cover the whole field of political and public life, and put the reader in possession of guiding principles which, in such crises as that we are now passing through, will be found as valuable as they are opportune. When the tumult and the din of an "appeal to the country" has subsided, and the

approach of autumn brings the weary professional man the holiday he has earned, we can imagine few pleasanter or more profitable *compagnons de voyage* than this compact little treasury of the wisdom and the wit of the two great masters of statecraft and "unifiers of empire." Be it remembered that in continental parliaments the physician and the surgeon are far more numerously represented than in our own, and that many of the discussions, of which this volume gives us the etherialized essence, were provoked or shaped by the interpellations of medical deputies. A Virchow in the German chamber, a Tommasi-Crudeli or a Moleschott in the Italian one, cannot fail to imprint their finely-trained intellects on the debates in which they take part, and it is one of the charms of Signor Mariotti's skilful compilation that not only does he make us hear Cavour and Bismarck at their best, but that he enables us to catch the echoes of far-reaching discussions to which the medical interlocutor has contributed the scientific thoroughness and the philosophic calm.—*Lancet*, July 17, 1886.

IMPORTED SMALL-POX.—The Brooklyn Board of Health has recently discovered fourteen cases of small-pox traceable to a Polish boy landed at Castle Garden three weeks before the discovery of the disease. It is said that there is a quarrel between the health officers on the lower St. Lawrence, and that quarantine is consequently in a very lax condition. It seems entirely probable that the States may have to quarantine against New York unless the officials in that State exercise more caution.

THE BRAIN OF GAMBETTA.—M. DUVAL (Director of the Laboratory of Anthropology) has recently given to the Society of Anthropology at Paris a detailed description of the external configuration of the brain of Gambetta. He draws special attention to the fact that the cortical structure in the neighborhood of Broca's convolution has become markedly augmented. Usually this part of the brain assumes the form of an M, the two vertical limbs or sulci enclosing a small valve-like portion in the shape of a V. In the brain of Gambetta, however, as has been noted in other cases as well, this V-shaped portion has become doubled on itself, and assumed the form of a W instead of a V. When we recall the fact that Broca, in his memoirs, attributes to this part of the cerebral cortex (left or right sided, according as the individual is right or left handed) the function of articulate language, the unusual development of this convolution in Gambetta and others confirms, to a certain extent, this opinion now generally accepted. Gambetta was a great orator, his memory for words being most remarkable. He had acquired a rapid and most exact method of expressing his ideas. It is, therefore, somewhat admissible to associate his great oratorical power with this increased growth of cortical tissue in the neighborhood of Broca's convolution.—*British Medical Journal*, July 31, 1886.

HOW TO INTRODUCE DISEASE.—The *Sanitary News* says: Importers of rags and paper stock feel

that they have gained an important victory now that the Treasury Department has been induced to change its ruling as to the bringing in of foreign rags. The recent order of the department does away with the compulsory fumigation and disinfection, the expense of which has caused so much grumbling in the trade.

"The health officer of the port still has the right to insist upon disinfection whenever, in his judgment, it is advisable," said a rag importer of New York recently, "but we don't anticipate the trouble and expense we have had with every cargo of rags heretofore. We shall have other importers in other lines of trade on our side in many cases, and the health officer will have to fight not the rag importer alone. For instance, if a vessel arrives with an assorted cargo, a portion of which is rags, and the health officer orders the rags to be disinfected, the consignees of all the rest of the cargo will be put to trouble and expense by the detention of the ship and the disinfection."

"Suppose an entire cargo of rags comes here; what will you do?" asked the reporter.

"Oh, we can avoid disinfection all the same. If a ship loaded with rags comes here we can stop her at Sandy Hook and order her to some other port where there is no disinfecting process provided, land the rags there, and then reship them overland to any place we want to."

A SANITARY convention will be held at Big Rapids, Michigan, on November 18 and 19, under the auspices of the State Board of Health.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM JULY 31, 1886, TO AUGUST 6, 1886.

Major Passmore Middleton, Surgeon, granted leave of absence until Sept. 10, 1886. (S. O. 100, Div. of the Atlantic, Aug. 3, 1886.)

Capt. R. H. White, Asst. Surgeon, ordered from Angel Island, Cal., to San Diego Bks., Cal., relieving Capt. Leonard Y. Loring, Asst. Surgeon. (S. O. 94, Dept. Cal., July 28, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING AUGUST 7, 1886.

Hutton, W. H. H., Surgeon, to proceed to Key West, Florida, for temporary duty. Aug. 7, 1886.

Bevan, A. D., Asst. Surgeon, ordered to examination for promotion. August, 1886.

Williams, L. L., Asst. Surgeon, when relieved at Buffalo, N. Y., to proceed to Mobile, Ala., for temporary duty. Aug. 2, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED AUGUST 7, 1886.

Rush, Chas. D., P. A. Surgeon, detached from the receiving ship "Franklin" and ordered to the U. S. S. "Pinta."

Willson, W. G. G., P. A. Surgeon, detached from the U. S. S. "Pinta," ordered home and wait orders.

CORRIGENDA.

In THE JOURNAL of August 7, p. 140, in Dr. H. T. Byford's article on the "Treatment of Retroversion of the Uterus" Cut 7 should be No. 9, 8 should be No. 7, and 9 should be 8.

In THE JOURNAL of July 31, p. 116, 1st column, 8th line from bottom, for "Thus 10 grains carb. of calomel and sulphate of quinine" read "Thus 10 grains each of calomel and sulphate of quinine."

ORIGINAL LECTURES.

SOME PRACTICAL HINTS UPON THE TECHNIQUE OF AN ASEPTIC SURGICAL OPERATION.

A Clinical Lecture Delivered in the Carnegie Laboratory,

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Reported by DR. H. SEYMOUR HOUGHTON]

GENTLEMEN—In finishing, this morning, the winter course of lectures upon the Principles and Practice of Surgery, I propose to give you some practical hints. These hints will have reference to the antiseptic precautions which should be observed in the performance of any surgical operation of great or small magnitude. If the principles upon which antiseptic surgery is based are true—and there is no doubt upon this point—it is necessary to observe the same care in opening an abscess as in opening a major joint or exposing the peritoneal cavity. You have doubtless been bewildered by all the suggestions which you have listened to from different surgeons in reference to the various methods of employing antiseptics. In my remarks to-day I shall confine myself to the different steps which should be observed in every surgical operation, if sepsis is to be avoided and primary intention is to be secured. I shall assume at the outset that you are all believers in antiseptic surgery, and that the ocular demonstration of the causes of decomposition and putrefaction, which you have seen here this session in the Carnegie Laboratory, have proved conclusively to your minds the truth of this great system of surgery.

At the beginning of the term you saw cultivations of the different micro-organisms upon Koch's sterilized jelly and other media. These micro-organisms were found in the air, in the water, and in the soil, and these same micro-organisms have been demonstrated to you to be the cause of putrefaction. You have seen in the clinics the beautiful results of surgical operations where means have been employed to prevent the access of these micro-organisms in wounds during an operation. You observe to-day that the infusions of beef in these test tubes, which were sealed last September, are as fresh this spring as they were last autumn. These pipette bulbs, which I exhibited to you in the autumn, are here again upon the table before me, and they remain unchanged.

No decomposition has taken place in the infusion which I sealed in glass tubes last August in Prof. Tyndall's laboratory in London, under the direction of Mr. Cottrell. These infusions of beef and of turnip are just as pure to-day as they were last summer. You also observe that this flask containing beef-tea, which was sealed last September, is still fresh and pure. I told you that I had seen flasks containing beef-tea which had been kept for ten years, and that there was no trace of decomposition in the infusion. All of these infusions contained in these various flasks upon this table have remained for months free from any contamination, and they will keep forever fresh and pure, because the micro-organisms which float in the air are prevented from coming in contact with the fluids.

The micro-organisms which cause the decomposition in the beef-tea, and milk and vegetable infusions, cause putrefaction in surgical wounds, and when the surgeon is enabled to operate under conditions which prevent the access of these germs into the wound, he will succeed in obtaining primary intention, in preventing suppuration, which is due to the presence of these germs in the wound. We have studied together this subject carefully during the present session, and I shall now endeavor to make a practical application of this knowledge to the treatment of surgical wounds.

In order to observe the small details of antiseptic surgery, one must have a sublime faith in its belief; because the smallest omission, insignificant as it may seem at the time, may be the cause of a complete failure. You will find some opposition to antiseptic surgery among a certain class of surgeons even at the present day. These surgeons will tell you that for over a half a century they have operated and with no precautions to prevent septic infection, and yet their patients lived, and the wounds healed. Many of you, upon your return home, will find that your preceptors are still unwilling to accept the modern views of the day. They will even deride you for the punctilious manner in which you conduct an operation, and boast that their cases recover without all the red tape and paraphernalia which you have been taught to observe. They even look upon you in disdain, and consider all your precautions as a species of pedantry characteristic of newly-fledged doctors. No great revolution has ever been undertaken without opposition; no reformation has ever been brought about without antagonism. As this is true in the political world, so it has its analogy in the

science of surgery. The opposition and antagonism are to be overcome, not by argument, but by persuasion, and by a reference to clinical facts. Compare the results obtained by the practice of antiseptic surgery of the present time with the results obtained by the older practice of fifty years ago, and an appeal to these facts in a kindly spirit will win over men when arguments will cease to convince. It is natural that men imbued with certain principles from their earliest days in the profession, will not change those views, which have already become fixed, to accept other views foreign to their education, and which views they are expected to accept upon the faith of others. You are to anticipate this opposition, and you are to meet it in a kind and friendly manner; and the time is not far distant when these very men will be convinced of their error.

Before considering in detail the steps necessary to the performance of any important surgical operation, I wish to call your attention to a practical point: always study your patient well before operating upon him or her. There is a good deal besides antiseptics to heed. The victory is not always due to the right use of antiseptics; but other factors enter largely into the calculation. Avail yourself of every possible means which will favor your patient. To this end examine carefully into the personal history. A knowledge of the condition of the heart, lungs, kidneys, and other organs, is essential. You should study his habits of mind and body, allay any anxieties on his or her part, assure the patient that all will be well, and encourage him or her in the hope that a speedy and certain recovery may be confidently expected. If the conditions of the patient do not justify you in such sanguine assurances, modify them according to the individual circumstances of the case, and use judgment and discretion. I believe that the mental condition of a patient has much to do with the prognosis, and that too much importance can not be attached to this fact. In every case you should aim to secure primary intention in the wound, with no constitutional disturbance, and for the accomplishment of these objects let me now direct your attention.

In every surgical operation, besides the general principles already enunciated, there are certain details to be observed, if the operation is to be aseptic, and the carrying out of these details will be considered under six different heads:

First. The disinfection of the operating room.

Second. The purification of instruments, etc.

Third. The preparation of antiseptic dressings.

Fourth. The disinfection of patient.

Fifth. The disinfection of operator.

Sixth. The application of the surgical dressing.

First. The Disinfection of the Operating Room.—

The day before the performance of any capital operation, especially if it be one in abdominal surgery, I would recommend the disinfection of the operating room. The room should first be scrubbed and dusted and made ready for an operation. I have used burning sulphur for disinfection. The sulphur should be placed upon an iron tray, which is set upon another and larger tray, and the sulphur is then to be

ignited. The tray should be placed in as close contact with the ceiling as is safe from fire, and the fumes of the sulphur will descend and fumigate the entire room. It is useless to place the tray upon the floor, because the gas will not ascend and no disinfection will be accomplished. With regard to the room in which an operation is to be performed in the country: In this case the necessity for disinfection is not so great; but if there has been any sickness in the house or any epidemic in the neighborhood, this process of fumigation is simple. A small room should be selected with southern exposure and the carpet and hangings removed, and sulphur can be burned for a few hours previous to a capital operation. If the room has been carefully scrubbed, cleaned and dusted, and then disinfected, you are safe from any local infection. It is always best to remove the carpet and hangings, because you need only a kitchen table and a stand in the room, and the continuous irrigation will do no damage if all the furniture is removed. The sheets and blankets for use during the operation should be loosely thrown upon the table during the fumigation. To some this step may seem superfluous and unnecessary; but in the event of a great operation every possible precaution should be taken to protect the patient from any infection, and no step is superfluous which has for its object the prevention of septic infection following any surgical operation.

Second. Purification of Instruments, Ligatures, Sutures, Sponges, etc.—Too much importance cannot be attached to a careful cleansing of all instruments for use during a surgical operation. Instruments for perfect disinfection should be of solid metal. The blade and handle should be of one piece and consist of a polished surface. I have abandoned the use of all instruments with ivory or pearl or wooden handles. They cannot be perfectly disinfected, and therefore the metal handles should be substituted. As far as possible forceps, and scissors, and all other instruments should be made to be taken apart and disinfected. I have here upon these tables a most elaborate display of surgical instruments, kindly sent at my request by Mr. W. F. Ford for purposes of illustration. Every instrument is made with the one object in view, and that is thorough and complete disinfection. All scalpels are made of one solid piece, and the handles belonging to the saws and chisels are solid metal. I should recommend you to purchase all instruments so constructed as to permit of perfect disinfection. Before an operation all the instruments to be used should be placed in a glass tray such as you see upon this table. I have requested Mr. Ford to import these glass trays from Germany, as they cannot be obtained in this country. Any glass or porcelain dish can be employed for the instruments; but these are so inexpensive and convenient that they will be found a valuable acquisition. Into these clean glass trays a solution of carbolic acid should be poured, of the strength of 1-20. There should be enough of the solution to completely cover the instruments, which should remain in this disinfecting fluid for an hour or two before an operation. The grease or dirt upon the instruments often prevents

the carbolic acid solution from disinfecting certain parts of the metal, and for this reason it is well to let the instruments soak for some time in the solution. Just before operating this solution may be diluted one half with warm water, 1-40, in order to avoid its destructive effect upon the hands of the operator. Carbolic acid is found to be the least injurious to the instruments as a disinfectant, and bichloride of mercury has been demonstrated to be most deleterious. The ligatures for use should also lie in another small glass tray which has a solution of carbolic acid, 1-20. As catgut is liable to become soft and unfit for use in carbolic acid solutions, it is best to preserve it, when not in use, in oil of juniper. About half an hour before operating, the catgut may be immersed in sublimated alcohol—*i. e.*, hydr. bichlor. gr. vijss to alcohol oj—and kept soaking there during the operation. Catgut is the best material for ligatures, as it is aseptic, will not cause irritation and becomes absorbed. Catgut has been shown to be the starting-point of infection, and therefore it should be obtained from a most reliable place. Catgut cannot well be prepared, and should be purchased only as needed. Silk ligatures, which can be used when the catgut cannot be procured in an emergency, can be, however, prepared by the surgeon without much difficulty. The formula given by Mr. Cheyne is a most useful one: take nine parts of beeswax, one part of carbolic acid, and melt these together. Let the silk lie in this until it is fully impregnated with wax and carbolic acid, then draw the silk through an aseptic towel and the friction will remove the superfluous wax. The ligatures can be cut and placed in a solution of carbolic acid, 1-20. The sutures can be made of catgut, or horsehair, or silk, or silkworm or silver; but whichever variety is used, the suture must be thoroughly disinfected, as well as the hare-lip pins. The lead buttons may be used to prevent tension in large wounds. The drainage is most important in every wound. This can be accomplished by means of tubes or by capillarity, as introduced by Mr. Chiene, of Edinburgh.

The drainage-tubes may be of rubber, and the red rubber is preferable because this kind of rubber tubing contains no free sulphur. The tube should vary in length and diameter according to the size, character and situation of the wound. The tube should have holes cut in it at short distances, and the tube when introduced into a wound should not project beyond the surface of the body, otherwise the tube is pressed upon by the dressings and bandage and the lumen of the tube is occluded. If the rubber tube is left too long a time in the wound it may become adherent to the wound by a process of adhesive inflammation and tear off, and part of the tube is then left behind in the bottom of the wound. This unpleasant complication I have lately had happen to me on two occasions, though the tubes were withdrawn within the required time. To obviate this accident I have of late used a tube made by Mr. Ford at my suggestion, consisting of pure ivory. This is polished smoothly upon its outer and inner surfaces. This tube will not collapse like the rubber tube, nor tear off, and possesses the special advan-

tage that it can be used more than once, as the ivory tube can be as thoroughly cleansed and disinfected for use in several operations. These tubes should be introduced by Lister's sinus forceps, and fastened by a disinfected safety-pin.

Drainage by capillarity is employed by strands of catgut which absorb blood and serum, but not pus. The threads of catgut are collected into a bundle, and this kind of drainage is not removed as the tubes are, since the catgut becomes absorbed. The ends of the catgut are left outside so as to produce a syphon action. Horsehair is also used instead of catgut; but the horsehairs are removed from time to time as it seems necessary.

Another method of absorbable drainage was introduced by Neuber, of Kiel. This consisted of bone tubes which were decalcified. An improvement to these tubes has been made by Mr. MacEwen, of Glasgow. The method of preparing these tubes as described by him is as follows: "The tibiae and femora of chickens are scraped and steeped in hydrochloric acid and water, 1-5, until they are soft. Their articular extremities are then snipped off with a pair of scissors; the endosteum is raised at one end and pushed through to the other extremity, along with its contents. They are then re-introduced into a fresh solution of the same strength until they are rendered a little more pliable and softer than what is ultimately required (as they afterwards harden a little by steeping in the carbolized solution). When thus prepared they are placed in a solution of carbolic acid in glycerine, 1-10." In ten days they are ready for use after holes have been punched in them. The tubes will last longer if instead of carbolic acid chromic acid is employed.

Protective oiled silk should be used over the line of suture to prevent the irritation of the carbolic acid, and also to prevent adhesion of the dressing to wound. This protective oiled silk can be made in the following manner as described by Sir Joseph Lister: Take ordinary oiled silk, paint it over with copal varnish, and when dry brush over the surface a mixture consisting of one part of dextrine, two parts of powdered starch, and sixteen parts of carbolic acid, 1-20. Carbolic acid will not permeate the oiled silk if the varnish is added, and the mixture permits the piece of protective to be moistened throughout so that dust will not collect in places upon the protective, as it does when the mixture is not employed.

The sponges to be used in every operation must be carefully disinfected, otherwise they may become prolific and dangerous sources of infection. The process of cleaning, bleaching and disinfecting sponges is very complicated, and I would suggest to you that the druggist do this, and when he has prepared them for you to carefully disinfect them, as this can be easily done by allowing them to stand in a glass fruit-jar containing a solution of carbolic acid, 1-20. The jar should be thoroughly disinfected before using it for this purpose, and it should be hermetically sealed at once and not opened until the operation. Any sponges which have been thus prepared and used can be cleaned by allowing them to

stand in water a few days, and this will decompose and wash out the fibrin contained in the meshes of the sponges, and then they are again put up in the hermetically sealed glass jars. The employment of sponges a second time may be considered safe, if the disinfective process is carefully carried out; it is, however, best in every great operation to prepare fresh new sponges.

Third. The Preparation of Antiseptic Dressings.

—There has always been more or less mystery, to say nothing of the expense, about the preparation of antiseptic dressings. It has been thought impossible to obtain them except through some especial agency. There is neither mystery nor expense about the preparation of these dressings, and I shall give you a few hints so that you can prepare them for any case and with but small expense. Every surgeon who practices antiseptic surgery has some modification of his own, and I shall only give you some general hints about the preparation of the dressings, so that you can have at command an easy and simple way of making antiseptic dressings. Bandages can be made by soaking cheese cloth for twenty-four hours in a solution of bichloride of mercury, 1-500, or carbolic acid, 1-20. The cheese cloth should be torn and rolled, and then disinfected again and wrapped in parafine paper and kept in an ordinary tin box, so that the bandages are kept from the air. Naphthaline gauze dressing is made by dissolving the crystallized naphthaline in alcohol (in saturated solution), but never in turpentine, as it is too irritating, and allowing the gauze or mull, which must be free from fat and acids, to soak for a day. This dressing is then dried by allowing the alcohol to evaporate, and the naphthaline powder will become crystallized, and then wrapped in the parafine paper and placed in a tin box.

Carbolized gauze can be made by using parafine, resin, and carbolic acid, and soaking the gauze in this mixture. Instead of using the gauze or mull, it is better to buy the von Brun's hospital gauze, which comes already prepared, and then disinfect it. The ordinary gauze must be subjected to some process to free it from the acids and fats, and this has already been done in the von Brun's gauze. The iodoform gauze is prepared by dipping the ordinary von Brun's hospital gauze, which can be purchased from any wholesale druggist, first into a bichloride solution, 1-1000, for a day, and then into a solution of alcohol and glycerine equal parts. The excess of alcohol is forced out by pressing and the iodoform powder is rubbed well into the gauze, when it is spread out upon a large plate of glass. Or the iodoform may be placed in a bowl and the damp gauze kneaded with the hands until the iodoform is evenly distributed in the meshes of the gauze. Bichloride gauze is prepared by soaking for twelve hours the von Brun's hospital gauze in a solution of bichloride of mercury, 1-500.

Combined dressings can be made by placing a thin layer of borated cotton between two layers of the gauze, which may have been soaked previously in naphthaline, or iodoform, or bichloride of mercury, according to the kind of antiseptic dressing required.

There are, of course, many other ways of preparing surgical dressings, but any surgeon, by following these simple instructions, can prepare for himself antiseptic dressings, and also find himself independent in this most important matter. All these dressings, while they can be made aseptic, have one objection in common, and that is the irritating effects upon the skin of certain individuals, and while this is oftentimes a serious objection, at present these dressings are the best we have. I have found the naphthaline in alcohol the only dressing which is less likely to irritate the skin.

Fourth. The Disinfection of Patient.—Any part upon which an operation is to be performed is to be made perfectly clean and aseptic. With this object in view the surface is to be washed well with soap and warm water, and then thoroughly scrubbed with a clean nail brush. After the scrubbing, which will remove the grease and dirt and epithelium from the surface, the part should be cleanly shaved with a sharp razor and then again washed, after which ablation the parts should be disinfected with a solution of bichloride of mercury, 1-500. This solution should be used freely and should be irrigated over the parts from an irrigator which is suspended. The vessel should be placed upon a shelf about six feet above the floor. The strength of bichloride can be 1-500 for the skin; but over a wound 1-2000 is of sufficient strength. If a joint is to be washed out 1-10,000 is strong enough, and if the peritoneal cavity is to be irrigated the solution should be very weak, as the extent of absorbing surface is very great. A part of the intestine could be irrigated by a solution of 1-10,000 if outside of the cavity of the peritoneum; but any solution within the cavity must be very weak. Boro-glycerine is the best solution for the peritoneal cavity. Patients are salivated by a continuous irrigation over an extensive wounded surface.

A rubber cloth is a necessary article during an operation. This should be well washed before using with a solution of carbolic acid, 1-20, or a bichloride solution of 1-500. The rubber sheet should be placed under the patient so as to be above the part to be operated upon, and should be gathered up and fastened by safety pins and the lower end be over a pail in order to catch the solution as it is irrigated over the parts before and during an operation. Long sand bags placed under the rubber sheet will form an artificial trough through and along which the irrigating fluid can flow. If the front legs of the operating table are elevated by placing two bricks or wooden blocks under them the force of gravity will cause the fluid to descend and fall into the pail or any receptacle at the end of the table. Clean towels should be wrung out in a warm solution of bichloride, 1-1000, and placed above and below and upon both sides of the part of the body to be operated upon, and fastened at the corners with safety pins so that the wound will not be touched with any part of the body, or any clothes upon the patient may not come in contact with the wound. Any instrument or sponge thus cannot come in contact with any surface which is not disinfected. After an operation all these

blood-stained towels should be removed and clean ones substituted before any permanent dressing is applied. A saturated solution of iodoform and ether or naphthaline and ether can be poured over the part before an operation; but after a thorough disinfection of the part in the manner already described. From the beginning to the end of an operation continuous irrigation should be kept up, so that the parts, and instruments and sponges and ligatures are continually saturated, and thus protected from any possibility of carrying infection. The strength of the irrigating fluid must be graduated according to the character and situation of the wound. This fact should never be lost sight of, that a safe irrigation for the skin is dangerous for a joint and fatal to the peritoneal cavity. The strength, then, of a solution for continuous irrigation must of necessity vary according to the nature of the part to be irrigated. As it is very desirable to have at hand a ready means of making these solutions, the formulæ of the two most frequently used will be appended:

1. For the *bichloride*, the surgeon should prepare a solution of mercury in glycerine as follows:

R.	Hydr. bichlor.	℥ij.
	Glycerine.....		℥iv.
M.			

This will give a strength of half a grain to the minim, so that, using this as a standard, and recollecting that 8 grains to the pint corresponds to 1-1000 (approx.), a solution of any strength may be readily computed. Thus, to make 1-1000, it is only necessary to add 16 minims of the glycerine solution to a pint of water, and this in turn may be diluted to any extent.

2. As alluded to above, the use of mercuric solutions is not devoid of danger, and hence, for other than surface irrigation—as in washing out suppurating cavities, *i. e.*, empyema—a milder and less irritating antiseptic is to be preferred. The material best adapted for this purpose is *salicylic acid* according to the formula of Prof. Thiersch:

R.	Acidi Salicylici.....	℥ss.
	Acidi borici.....		℥ss.
M.	Ft. pulv. No. 1.		

These powders may be kept on hand, and adding one to a quart of warm water, a solution of convenient strength is secured.

Fifth. The Disinfection of the Operator.—The surgeon and every assistant should be scrupulously clean. The hands should be washed in warm water and soap and scrubbed well with a nail brush and then dipped into a vessel containing carbolic acid or bichloride of mercury. After the hands have thus been washed and the finger-nails cleaned and then disinfected, no towel should be used to dry the hands, for the towel itself may become a source of danger. A rubber apron, previously disinfected, should be worn, and over this a clean white linen apron should be placed, which apron has been carefully prepared by a competent nurse. What has been said in reference to the operator and his assistants is likewise applicable to the trained nurse who is in attendance upon the case, as well as all others who assist in the toilette of the patient. In pointing out these few practical hints in reference to the preparations which should be made

for every surgical operation, I do not wish that it should be understood that there is any desire to adhere to one antiseptic solution in preference to others, or to commit myself to any one solution.

The solutions which have been recommended in the lecture this morning are those which up to the present time have been found by the majority of surgeons to be the most satisfactory when all things are taken into consideration. I do not hesitate to state that in my own experience I have seen serious trouble arise from the use of any and all of these solutions. In this bottle is urine which is nearly black, and it was voided by a patient who was obliged to submit to paracentesis thoracis, and the spray of carbolic acid for a few moments thrown upon the chest wall had given rise to this condition of urine. The use of carbolic acid as a disinfectant not only poisons the patient occasionally, but it has been known to produce acute albuminuria in surgeons. Thus it is evident that carbolic acid, while it is the best disinfectant for instruments, sponges, and the surgeon's hands, has nevertheless some serious objections.

Bichloride of mercury is most useful for continuous irrigation, and is perhaps one of the best germicides that can be employed; but it, too, has its objections. Bichloride of mercury ruins surgical instruments, will often produce salivation of patient, and more often will excoriate the skin over whatever part it is used in a dressing.

The question naturally suggests itself to you at this point, what is the best solution to use? I have found sulphurous acid the best for continuous irrigation; but while it is the most efficient germicide, the gas cannot be kept in solution for the purpose of making surgical dressings as the gas escapes from the gauze. Hyposulphite of soda is another excellent solution, and possesses the special advantage of being useful as a disinfectant for instruments, the hands of the operator, for the preparation of surgical dressings and for continuous irrigation; but it has one great disadvantage which prevents its use, and that is the slippery feeling it gives to ligatures and to the surgeon's fingers. Naphthaline is also good for dressings; but it is difficult to get a pure article, and the impure powder is deleterious. I have mentioned these facts simply to show how difficult it is to procure one solution which is applicable for disinfecting instruments without injuring them, for washing the hands without producing unpleasant effects, and finally, for preparing surgical dressings. It is for these reasons that I have already mentioned that up to the present time there is no one germicide which can be used in common for disinfecting instruments, purifying the hands, and preparing dressings. The subject of an efficient germicide with no disadvantages is one still under consideration by surgeons, and until such a perfect germicide is discovered we must be content with what we have at present in use, and employ our solutions with great care and avert as far as possible the serious objections which we find in their use.

An ideal solution is one which can be employed for disinfecting instruments and ligatures and sponges

without detriment, and at the same time be used for continuous irrigation without injury to the patient or to the surgeon, and also one which is easily made and which is economical, and which will not become volatile or render the fingers slippery, or lose its germicidal effect by evaporation. It will be a great advance in antiseptic surgery when a single solution is discovered which will answer all the essential conditions. The great principles of antiseptic surgery will thus be simplified and within the reach of all to carry out in daily surgical practice. The great difficulty heretofore in carrying out the principles of antiseptic surgery in the practice of those not especially educated in this department of surgery has been in the fact that there has been no unanimity of opinion among surgeons as regards the relative value of the different germicidal solutions. Another difficulty has arisen in the fact that one solution of a certain strength must be employed for instruments and another solution for the surgeon, and still another for irrigation, and again another for the dressings. This has led to confusion, and when an ideal solution is found all this technique will be simple instead of complex, and the merest tyro in surgery can carry out the principle upon which this great system of surgery is based.

Sixth. The Application of the Antiseptic Dressings.—Too much importance can not be attached to the permanent dressing after an operation has been performed in an aseptic manner. Carelessness on the part of the surgeon in the application of the dressings may result in complete failure to secure primary intention. The wound should be perfectly dry and free from all loose coagula before the sutures are introduced. The kind of drainage to be employed depends upon the character, situation, depth and size of the wound.

If the wound be small, as, for example, after osteotomy, the strands of catgut inserted into the bottom of the wound with the ends left hanging out of the lower angle of the wound will be found a most efficient and excellent method. If the wound, on the other hand, be large, then a red rubber drainage tube, or the ivory tube on the glass canula, will be found to be the best for providing an escape for the inflammatory exudates which are always present after an extensive wound. The sutures should be of catgut for small wounds; but silk-worm, or silk, or silver, should be employed in amputation wounds or any wounds of considerable size. It is not safe to rely upon catgut if there is likely to be any tension in the wound. I have found that catgut is good for superficial sutures, while the silk-worm or silver, or even hare-lip pins, are best for the deep sutures.

After the edges of the wound are nicely and accurately adjusted by cutting away with a pair of scissors, curved on the flat, any loose fatty or connective tissue which insinuates itself between the lips of the wound, the sutures should be tied, and if any tension exists the button suture can be employed with great advantage. The surface of the wound should now be irrigated for the last time, and then iodoform or naphthaline powder be dusted over the linear incision and then protective placed over the wound, and

finally a bandage, which is wet with a bichloride solution, wrapped around the part. The wound is now protected and the surrounding parts are to be carefully dressed. A layer of the combined dressing should now be made to envelop the part at a good distance in every direction from the original wound. This combined dressing should be made secure by an antiseptic bandage. If the wound be a fracture, a plaster-of-paris bandage can now be applied and a layer of borated cotton can be first wrapped about the whole limb before the plaster-of-paris bandage is applied.

If the wound be dressed in general in some such way as has been described, this first dressing need not be disturbed for eight or ten days, unless for the purpose of removing the drainage tube, which can be done without taking down the entire dressings. If the dressings be stained with serum, or there be any other discharge, this first dressing should be removed and a clean new one applied with every antiseptic precaution. It is well in every case to change the dressings after eight days, even if there seems to be nothing wrong. A neglect of this rule has been followed, in my own experience, by some unpleasant complications, and I believe that every surgical wound should be examined as a matter of precaution. I have seen serious trouble occur when a fracture dressing was cut down at the expiration of six weeks; although there never was any evidence or sign of trouble during the six weeks. Whenever a dressing is removed and a new one applied the same attention to details and the same antiseptic precautions should be observed as during the application of the first and original dressing. Carelessness on this point has been followed by suppuration in a wound which had nearly completely healed by primary intention. Every surgical dressing, be it the first or the last, in the history of any wound, should be made with the same care and attention.

Another point seems to me of great importance in the treatment of every wound, and that is the maintenance of absolute rest to the part during the repair of the wound. The equable and uniform pressure upon the wounded part secured by the combined dressings which have been described, are inadequate to secure mechanical fixation to the part without the aid of splints so applied as to maintain physiological rest to the wounded part, as well as the parts in the vicinity of the wound. Every surgeon has his own peculiar way of applying his dressings, and the method which has been described is only intended to impress the general principles involved in wound treatment. The great principles of absolute rest, of free drainage, of uniform compression, of freedom from pain, of absence of constitutional disturbances, together with many other salient principles, are thus maintained by these simple rules in the application of surgical dressings.

Now, gentlemen, having completed the operation with every antiseptic precaution, you are justified in the belief that all will go on well to a successful and and rapid recovery. Should anything happen to prevent primary intention in the wound, you must carefully search for the cause and remedy it at once.

The triumphs of antiseptic surgery are so numerous and so uniform that the cause is to be found in the omission on your part of some detail in the technique of the operation. Look always for the cause to some defect in your manner of operating, or in the use of your antiseptics. If you fail in your first attempts, inquire rigidly into the cause of failure, and do so with the positive assurance that the fault is with you and not with the patient or the system of surgery which you have attempted to practice. It is with this spirit that you should adopt the great principles of antiseptic surgery, and when you are fully convinced by actual experience what great things can be accomplished you will not wonder that hundreds of operations can be consecutively performed and the patients escape from septic infection. We can do now what could not be done a few years ago, and I trust that you may all participate in the great work, and contribute much to the science which we have studied together, and which offers to suffering humanity assistance such as never could be proffered before the introduction of antiseptics.

ORIGINAL ARTICLES.

SOME CASES ILLUSTRATING THE SAFETY OF COCAINE AS AN ANÆSTHETIC IN CATARACT EXTRACTIONS.¹

BY GEO. E. FROTHINGHAM, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF MICHIGAN.

During the past year several experienced operators have published cases and experiences that would seem to condemn cocaine as one of the most unsafe anæsthetics to use in the extraction of cataract. Notable among these we may mention the observations of Nettleship, McHardy, and Browne,² who have cited their experiences to show that the use of cocaine has a great tendency to produce panophthalmitis in eyes operated on for the extraction of cataract under its influence. Pfüger charges it with producing neuro-paralytic keratitis as a sequel to operations of this kind made under its influence. Dobrobofski, in a quite large per cent. of his cases, had prolonged nausea and vomiting follow as a result of using a four per cent. solution. Traumatic keratitis, tardy and imperfect healing of the wound made in the extractions, were noticed also as a complication in his cases, and ascribed to the cocaine. Bunge reports three complications apparently caused by its use in the clinic of Graefe, at Halle. These were: destruction of corneal epithelium; vesicular eruption on the cornea; and parenchymatous corneal opacity. By this opacity it destroyed the eye in some of the cases, and impaired vision seriously in six cases out of a total of 150.³ Many other observers have attributed bad results to the action of cocaine.

¹ Read in the Section on Ophthalmology and Otology, at the Thirty-seventh Annual Meeting of the American Medical Association.

² British Medical Journal, Nov. 21, 1885.

³ Ophthalmic Review, Nov., 1885, p. 338.

With a view of contributing to a settlement of the question as to whether any of these results may be fairly charged to the action of cocaine, I have thought it worth while to contribute my experience with it in the extraction of cataract, which I present in the form of a table prepared for me by E. B. Patterson, clerk of the ophthalmic clinic under my charge. (See table on following page.)

A smooth operation was obtained in every case but one (No. 21). In this case a slight escape of vitreous occurred before the iridectomy was completed. The lens was drawn out in its capsule by means of a sharp hook, without further loss of vitreous, and a good result was obtained. V. = $\frac{2}{3}$. There was entire freedom from nausea and vomiting in all the cases in which cocaine was employed as an anæsthetic. Only fresh solutions of cocaine were used.

These constitute all the cases of cataract extraction performed by me at the public clinic from October, 1885, to May, 1886. Although alone insufficient to establish or contradict any of these claimed dangers from the effect of cocaine, they will serve to add to the great mass of statistics by which the questions referred to must ultimately be settled, and which will require the united reports of numerous operators. By reference to the table it will be seen that in thirty-nine extractions made since October 10, 1885, cocaine has been the anæsthetic used in thirty-one of the cases. In thirty of these a four per cent. solution was used. In one case, a feeble lady of 80, a two per cent. solution was substituted. Cocaine failed to act as an anæsthetic in three of the thirty-nine cases, and ether was selected on account of the timidity of the patient in four of the cases. The result was good in thirty-six of the thirty-nine cases, improved in two of the cases, and in the other case, in which the patient died of diabetic coma on the 7th day, the result of the extraction was perfect. There was no complication whatever as far as the healing process was concerned. The vision was clear at the first opening of the eye, and remained so up to the time of the patient's becoming unconscious, a few hours before her death. The other two cases were congenital cataract, which had been neglected beyond the period which permits of good results. In these cases degenerative changes called for extraction. In one, operated on under cocaine, vision was much improved, and no complication occurred during the healing process. In the other ether had to be resorted to; slight iritis followed the operation. The patient improved, and is still gaining in visual power.

No inflammatory complications occurred in thirty-four of the thirty-nine cases. Iritis occurred in four of the cases, in two of which ether was the anæsthetic used.

In about seven hundred cataract extractions I do not remember so large a number of consecutive cases that presented so great freedom from inflammatory trouble, either of the cornea or deeper structures, though I have had a larger number of consecutive cases in which perfect results were ultimately obtained, and also with better average of vision. Nor

have I had so remarkable freedom from nausea and vomiting after the extractions as when ether or chloroform were used, saying nothing of the embarrassment from this cause that so often occurred during the operation when made under these anæsthetics, and which has deterred some operators from resorting to them. By using cocaine we also avoid that agitation of the patient which results from excessive bronchial secretion, so often produced when ether is used. Indeed, in my experience, so often is the patient unpleasantly affected from this action of ether, and the obtaining a smooth operation endangered by it, that I have been in the habit for years of substituting chloroform in all such cases, believing that the increased risk to the life of the patient arising from this substitution is warranted in view of the greater certainty of obtaining a smooth operation, and thus increasing the chances of restoring sight.

From my own experience, I am inclined to regard cocaine as the safest anæsthetic we possess for use in cataract extractions, so far as subsequent complications are concerned. While it may, by its vaso-motor constriction, or paralytic action, temporarily diminish the nutrition of the cornea, I believe *that* impairment to be only brief, except in rare cases. I believe it is no more likely to interfere with the healing of the wound in this way, than the general depression arising from the effect of chloroform. From what we, at present, know concerning the action of each of these anæsthetics, it is rational to suppose that there is far less disturbance of the interior circulation of the eye produced by cocaine than by either of the other two, and consequently less liability of panophthalmitis following its use in these operations. So far as its effect to produce shedding of the corneal epithelium is concerned, in most of the cases I have seen reported, antiseptic solutions had also been used, and I am inclined to ascribe this corneal complication to some carelessness in the use of these solutions, rather than to the effect of cocaine. At any rate, it has never been observed by me to follow the use of cocaine when resorted to for this or any other purpose. Solutions of cocaine, when kept for more than a few days, or gelatine tablets containing cocaine (as they are hygroscopic and liable to change), may be attended with danger when used in operations upon the eye.

In reviewing these cases, cases nineteen and thirty-two are worthy of brief special consideration. Case nineteen illustrates how guarded must be our prognosis in all cases of diabetic cataract. This patient had not been aware of her condition, and was made acquainted with it only through the investigations I insist upon as preliminary to cataract extractions. Among these preliminary examinations I insist upon an analysis of the urine. This has been my custom for many years. For the past few years I have been especially urgent upon this point by reason of an unfortunate result that occurred in a case in which I had neglected it, and was thus unprepared to expect misfortune. A lady about 60 years of age presented herself at my clinic having the appearance of a person in good health, and claimed to be perfectly well. She was blind from

senile cataract, both lenses presenting the peculiar amber hue, and there was apparently no complication. She was very urgent for an immediate operation, and presented reasons that induced me to yield to her request, and without waiting for the usual urine analysis I operated, using ether as the anæsthetic. The patient suffered from prolonged nausea and vomiting and seemed not fully to recover from the effect of the anæsthetic, and died of coma about ten days after the operation was performed. The wound had healed nicely and the eye presented no sign of complication. Examination of the urine made during the illness showed both albumen and sugar, and an autopsy revealed that the patient suffered from that somewhat rare combination of Bright's disease and diabetes mellitus. Recognizing the injurious effect of ether in Bright's disease, I blamed myself for administering it in this case without knowing the condition and warning the friends of the increased danger.

In case 19, however, we had the diagnosis clear before the operation. As cocaine relieved us of the constitutional disturbance incident to a general anæsthetic, and the patient was courageous, urgently soliciting the operation, and cheerful during its performance, there was no reason for expecting that the extraction might hasten the fatal issue of the disease. All this was duly considered in my discussion of the case before the class, and I had also stated the uncertainty of life in any of these cases. I was not, however, prepared to expect a fatal termination of the disease in this case so soon. The result shows us how careful must be our prognosis as to life in such cases, though it should have no effect to deter us from operating when a person is blind from diabetic cataract and presents no evidence of immediate danger from the constitutional disease. If the patient lives but a few weeks, the blessings of sight will be a sufficient reward for all he endures, and with cocaine we may expect to perform the operation on courageous and hopeful patients with no fear of hastening the fatal issue. Neither can cocaine or the operation be charged with the result in this case.

Case 32 illustrates the favorable results that sometimes come from apparently hopeless operations, and shows that cocaine may be used safely even when there is increased tension. He began to notice dimness of sight about three years ago, the sight failing slowly but constantly. There was no pain until about three months preceding his appearance at my clinic. During these three months he has had slight pain in eyes, and headache. The left eye was entirely blind; he could not perceive the brightest light, pupil dilated and would not respond to brightest light, lens opaque and pressing against the cornea, + 72, no pain at present. Right eye perceives bright light, pupil dilated and responds slightly and slowly to bright light, lens opaque and bulging into anterior chamber, which is almost completely obliterated, + 71, no pain at present, a few enlarged anastomosing veins in ciliary region. This patient was told that there was no prospect of a successful operation, but at his urgent request it was undertaken on right eye, thinking it possible to preserve perception of

light for awhile longer and perhaps enable him to see large objects. On March 20 a large iridectomy was made, using cocaine as the anæsthetic. The anterior chamber was so nearly obliterated that only by careful use of Graefe's knife could a small incision into the anterior chamber be made, and this had to be enlarged greatly by the scissors to allow a sufficiently large piece of the iris to be seized and excised.

April 3.—The patient has very completely recovered from former operation. Tension normal, and anterior chamber nearly of normal depth. Cocaine was used and lens extracted. Operation smooth, and no after complications occurred.

April 26.—Eye tested, and with $+ \frac{2}{3}$ S. V = $\frac{2}{3}$ sharp. Ophthalmoscopic examination showed results of serous choroiditis and there was choroidal atrophy about the disc, but no excavation of disc itself. As regards the action of cocaine, the results in these cases would tend to establish the following propositions:

1. Cocaine relieves the operator from the embarrassments during the operation for cataract that arise from vomiting; also from the agitation of his patient which results from excessive bronchial secretion, or stertorous breathing. These are often very troublesome when ether or chloroform is used.

2. The danger to the result which often arises from nausea and vomiting after the extraction, when other anæsthetics are employed, is very surely avoided when cocaine is selected as the anæsthetic agent and is properly used.

3. The danger arising from the depressing effect of cocaine upon the nutrition of the cornea is no greater than in cases where ether or chloroform are used. The depression of the circulation, which often arises from either of them, may affect very injuriously the corneal nutrition.

4. The disturbance of the circulation of the interior of the eye, and consequent danger of panophthalmitis from this cause, is probably less in using cocaine for this operation, than in resorting to general anæsthesia.

5. The danger of sepsis and consequent panophthalmitis from the use of cocaine may be avoided by using only fresh solutions.

AMPUTATION AT THE HIP JOINT FOR MORBUS COXÆ; WITH A CASE AND A SPECIMEN.¹

BY DONALD MACLEAN, M.D.,

OF DETROIT, MICH.

The points which I desire especially to enforce by the following case are:

First.—That there are cases of hip joint disease which, though utterly desperate so far as all the ordinary procedures are concerned, may still be rescued and restored to health by the extreme measure of *amputation at the hip joint*.

Second.—That the operation of resection, if performed at all, should be performed at a much earlier stage of the disease than has hitherto been customary.

¹ Read before the Surgical Section of the American Medical Association, at the Thirty-Seventh Annual Meeting.

Third.—That with proper precautions, the operation of amputation at the hip joint for disease is a safe and satisfactory procedure.

Case.—C. S. B., æt. 17, from Muncie, Ind., came to my public clinic at the University of Michigan January 5 of the present year, and in response to inquiries made the following statement:

Eight years ago, he fell on the ice and sustained a contusion of the left hip. Still, it was not until the following winter that he became so much disabled as to require the aid of a cane in walking. Liniments and electric baths were prescribed at that time, but of course they did not do any good. Two years later extension by means of the weight and pulley was resorted to, also an extension splint, but in spite of these very judicious and rational measures the disease continued to progress.

Eighteen months ago an abscess formed in the region of the trochanter major and was opened. Before long an abscess formed on the inner aspect of the thigh and was opened. From these abscesses sinuses resulted, which have continued to discharge ever since. At the time of his admission into the University Hospital, the discharge from these sinuses was not extremely profuse, but it was intensely fetid. He was greatly emaciated, and suffering from marked hectic symptoms. The thigh was flexed to a right angle with the trunk, and there was no movement discoverable in the hip joint. The knee joint was also flexed and partially ankylosed. All the muscles of the limb were contracted and atrophied. Under these circumstances resection of the joint was at once and for obvious reasons excluded. In short, it seemed that the choice lay altogether between one or the other of the two following alternatives:

First. *Expectancy*, which of course promised only speedy exhaustion.

Second. Amputation at the hip joint, and this operation commended itself to my mind as a justifiable and even hopeful expedient, provided, *first*, that the pelvic bone should on examination prove to be fairly healthy—that is to say, not too far involved in the carious affection; and *second*, that the general powers of the patient's constitution had not been too thoroughly undermined by the long-standing and exhausting disease. The proposition having been fully explained to the patient (a most intelligent young man), he eagerly assented and placed himself in my hands.

The final decision as to the condition of the os innominatum was reserved till the time of the operation, and had it been found too far diseased the completion of the operation would have been abandoned as useless and unjustifiable. Fortunately, no such reason for the abandonment of the operation was met with. The disease was confined entirely to the acetabulum, and even there was quite superficial and small in extent.

So far as the strain on the patient's weakened powers was concerned I succeeded in convincing myself that, provided due precautions against hæmorrhage and shock were used, he would be able to weather the storm. With this object in view I determined to

use a simple and somewhat primitive form of aortic compressor: an instrument made under my own directions some years ago by a common blacksmith, and which has afforded me indispensable aid in a considerable number of instances.

The operation was performed on March 1, 1886, under chloroform. Hardly a drop of blood was lost. The patient was only a few minutes on the table. The degree of shock was very slight.

The wound was treated antiseptically throughout and healed rapidly, so that on April 9 the patient was able to return to his home in a better state of health than he had known for several years. Reports received up to the present time have been altogether favorable. I now present for inspection by the members of the Section the femur of this patient. It will be observed that the disorganization of the medullary canal extends from the one end of the bone to the other. Also, that the head of the bone is very nearly all absorbed away. A single glance at this specimen is sufficient to determine effectually the question of the propriety of the operation; or at least the utter hopelessness of the case without this measure.

Finally, I think we may safely deduce from this case the general principle that if resection of the hip joint is to afford permanent satisfaction, it must be performed at a much earlier stage of the disease than has heretofore been customary; that is to say, while the disease is limited to the head of the bone, and before the medullary canal of the femur has become involved, which it is certain sooner or later to do.

MEDICAL PROGRESS.

RESORCIN.—The *Centralblatt für die ges. Therapie*, March, 1886, contains the following observations concerning resorcin by M. IHLE, of Leipzig, reported by Jarisch. The specific antiseptic properties of resorcin can be best noticed in herpes tonsurans. After two or three applications of a strong resorcin ointment the inflammation is allayed, and if the plates of epidermis tanned by the resorcin are removed, it will be found that only in those hairy regions where the spores have made their way to the bottom of the hair follicles it is necessary to continue treatment.

A very great advantage in the treatment of parasitic sycosis with resorcin is that the beard need not be epilated, the hairs loosening of themselves under the treatment. The pastes used should be applied two or three times a week, thickly with a brush, and rubbed well into the parts, which are then to be covered with cotton. It is at all times well for the physician to apply the preparation himself, and increase the strength with the progress of the cure. For instance, if the first application is a 10 per cent. paste and causes no great irritation, the next may be of 25 per cent. and the strength may be thus gradually increased to 50 or 80 per cent., then when the pus formation and irritation begin to decrease, applications must be continued in decreasing strength, following a similar scale.

As spores may still exist in a case of apparent cure, it is advised to give the patient a 3 per cent. salve to apply at first daily, and later on once or twice a week. Now, for the first, should shaving be permitted, because in the energetic treatment with resorcin, shaving should be absolutely forbidden on account of the irritation which it causes.

The following ointments are recommended:

R	Resorcin purissim.....	10
	Vaselini albi.....	50
	Amyl. Oryzæ,	
	Zinci Oxidi.....aa	25
M.	ft. past.	

With an increase in the amount of resorcin, it is necessary to decrease proportionately the zinc and starch. Therefore for stronger ointments, the following is used:

R	Resorcin puriss.....	50
	Vaselini albi.....	60
	Zinci Oxid.,	
	Amyl. Oryzæ.....aa	20
M.	ft. past.	

The author speaks of resorcin in the treatment of pityriasis versicolor and eczema marginatum as being attended with absolutely sure results. He also recommends it in the treatment of alopecia areata and seborrhoea cum defluvio capillorum.

For these he uses:

R	Resorcin puriss.....	5.10
	Ol. Ricini.....	45.
	Alcohol.....	150.
	Bals. Peruv.....	0.5
M	S. Apply daily to head with a flannel rag.	

The itching of the seborrhoea is said to cease entirely under this treatment.

Condylomata acuminata treated with an eighty per cent. resorcin salve, daily applied, quickly disappear. It is well to apply a five to ten per cent. salve for some time afterward to remove the tendency to their redevelopment.

Dr. Ihle does not approve of the application of resorcin to eczema and other inflammatory skin diseases, because of its irritating properties.

Dr. Unna, however, in a pamphlet upon Ichthyol and Resorcin (Hamburg and Leipzig, 1886), recommends a five to ten per cent. ointment in the treatment of seborrhoeic eczema resulting from alopecia areata, and prefers it to ichthyol or pyrogallie acid.

He mentions as a special advantage its lack of color and freedom from staining. In psoriasis its action is not so favorable, but for all dry scaly eczemas of the face he recommends it.

On account of the difficulties of diagnosis in skin diseases of the face, he advises that the drug be discontinued the moment it is noticed that no improvement is taking place. In scars or pitting from variola, traumatism, acne, or other cause, and in false keloid he has found it of benefit, but its advantages over ichthyol and other reducing substances lies wholly in the fact that it does not produce discoloration and does not inflame the eyes as does chrysarobin, although under certain circumstances the latter drugs have preference. Dr. Unna declares himself quite convinced that in acute exanthema, and espe-

cially in scarlatina and variola, resorcin is destined to play a very important part.

In chronic skin diseases its use must remain limited to external application.—*Journal of Cutaneous and Venereal Diseases*, August, 1886.

THE CONNECTION BETWEEN GLYCOSURIA AND BILIARY OBSTRUCTION.—DR. W. A. WYATT says it has been demonstrated by Dr. Wickam Legg, and confirmed by Von Wittich, that ligation of the bile-ducts causes the disappearance of glycogen from the liver, and that after ligation glycosuria cannot be produced by puncture of the floor of the fourth ventricle or section of the cervical sympathetic. It is presumed that the retention of bile within the liver interferes with the nutrition of the hepatic cells, and so prevents them from carrying on their natural function of glycogen formation.

The following clinical case appears to me to support the conclusion drawn from the above mentioned experiment. A lady, aged 60, has for some time suffered from glycosuria, and latterly albumen has been present in addition; the amount of sugar excreted usually ranges from 10 to 12 grains per ounce, and no material alteration in this quantity occurred when the urine became albuminous. The urine has been always highly saccharine, even when a strictly nitrogenous diet was enforced, a symptom pointing to the fact that a too rapid metamorphosis of hepatic glycogen was the probable source of the excess of sugar in this case. A short while ago this patient became jaundiced, the urine containing both biliary acid and coloring matters, and with the appearance of the jaundice the sugar diminished from its usual amount to a hardly perceptible trace, Fehling's reagent, the picric acid and indigo carmine tests, giving almost negative results. The disappearance of the sugar could in no way be accounted for by alterations in diet, for the appetite and manner of living remained the same as usual. In this, case, however, there was undoubtedly some obstruction to the bile-ducts, as no bile could be detected passing with the stools, so that a pathological condition was here established analogous in its result to the experimental ligation, for in each case the escape of bile was effectually hindered. If, then, it is correct that the retention of bile within the liver prevents the formation of hepatic glycogen, it necessarily follows that the same retention must greatly diminish the amount of sugar in a case of glycosuria of that type in which the disease is chiefly dependent on a too rapid metamorphosis of glycogen into sugar. In making deductions from a single case, it is well-nigh impossible to separate the *post hoc* from the *propter hoc*; but at any rate, in this case, coincident with the retention of bile, the amount of sugar excreted fell to zero, and remained so as long as the obstruction lasted—speedily, however, regaining its usual amount of 10 grains per ounce as soon as bile was again poured into the intestines.

The whole subject of glycosuria up till now has been elucidated more by the experimental physiologist than by the physician. However valuable such experiments may be, the results obtained from them are often very fallacious, the condition under which

they are conducted in many cases being far removed from anything existing in nature, so that confirmation of such observations by clinical work is always highly satisfactory. Of course the phenomena of this case may bear an interpretation differing widely from that which I have assigned to them; still I venture to think that the biliary retention being accompanied by an almost entire absence of sugar in the urine was not a mere coincidence, but that the two symptoms were related to each other as cause and effect.—*Lancet*, May 15, 1886.

HOT BATHS, HOT PACKS, AND PILOCARPINE COMPARED.—DR. ZELENETSKI, of St. Petersburg, in order to examine the comparative effects of hot baths, pilocarpine, and hot wet sheet packing on nephritis, treated the same patients on different days by means of each of these methods, observing the effects on the temperature, pulse, etc. Fifty-seven observations were made on seven patients, who were as nearly as possible under identical conditions. Twenty-three baths, eighteen hypodermic injections of pilocarpine and fifteen hot packs were given. The hot baths produced the greatest loss of weight, averaging 801 grammes, and the packing the least, averaging 94 grammes, pilocarpine producing effects of an intermediate character. Here the mean loss of weight was 514 grammes—306 by perspiration, and 208 by salivation. The temperature rose considerably after the baths, and even at the end of three hours was always above normal. The packing caused it to fall at first; but after an hour it rose, and returned to its original height within three hours. With pilocarpine it was reduced for two hours, and then rose to normal. The pulse corresponded to the temperature with the baths, but became slower with both packs and pilocarpine. The patients expressed themselves as feeling the most improvement after the baths; the pilocarpine causing complications, such as headache and nausea, and in one case vomiting and collapse.—*The Lancet*, June 12, 1886.

THE TREATMENT OF PELVIC HÆMATOCELE BY GALVANO-PUNCTURE.—APOSTOLI and DOLÉRIS, *Zeitschrift für Therapie*, 1885, No. 18, recommend this treatment, their method of operating being as follows: Having carefully determined, by means of rectal and vaginal examinations, the precise relations of the tumor, with special reference to the presence of surrounding intestines or large vessels, they plunge into its most prominent part a needle connected with the negative pole, the positive (consisting of a disc of potter's clay) resting upon the abdomen, and pass as strong a current as can be obtained by a Leclanché battery. The séance lasts from five to ten minutes. A fistulous opening is established in the vaginal fornix, which is kept patent; if it closes prematurely, it is reopened by a second application of the needle. After being opened, the sac is to be irrigated twice daily with an antiseptic solution. The only danger in this operation, according to the writers, is the accidental puncture of a large vessel, the hæmorrhage from which is readily arrested by the cautery.—*New York Med. Journ.*, July 31, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

POISONS IN FOOD AND DRINK.

As it is fitting that the public should be made aware of the dangers that threaten health and life in food and drink, it is also fitting that such information should come from those who are not only entitled to speak with authority, but who are well known to the outside world. In the August number of *The Forum* is an article, by DR. CYRUS EDSON, of New York, on this subject in which sound ideas as to food and drink are plainly set forth, in language which anyone may understand. The American public is taking more interest in matters of public health each year. Articles on sanitary subjects in newspapers and magazines, sanitary conventions, more of them each year, and the American Public Health Association, and we should not forget to name also the various State and local Boards of Health which are becoming more numerous each year, have given a wonderful impulse to sanitary thought and procedures during the last two or three years. The public is beginning to learn that the necessary results of the neglect of sanitary laws cannot with justice be laid at the door of Providence.

In the article referred to Dr. Edson first deals with drinking water. "How rarely do we stop to consider before drinking a glassful whether it is pure or not? If it be clear and cold, we are satisfied." It would be well if every physician would closely investigate the sources of the drinking water supplied to his patients. Medicine may avail but little if the pig-stye be within a few feet of the well from which the water is obtained. "Given the conditions under which a well exists, it is no more necessary to analyze its water to ascertain its character than it is to analyze the air of

a room connected directly with a city sewer to find out if it contains sewer gas. The depth of the well, whether it be walled or piped, the character of the substrata, the proximity of contaminating influences and their amount, are the only factors to be considered." From a consideration of water he passes to that of ice and ice supply. "The idea that water purifies itself by freezing is very prevalent and very deeply rooted. It has led to the use of ice from ponds, the water from which no one would think of drinking. It is true that a few of the solid contaminants may settle and be eliminated in freezing, but that water once polluted is thus rendered safe is a theory long since exploded. Degrees of cold sufficient to kill diseased germs are never experienced in temperate zones. The germs which caused the Plymouth outbreak of (typhoid fever) were shown to have been exposed for three days to a temperature of 20° Fahr." The ice supply should receive as close attention as the source of our drinking water.

Few people understand that it is more than swindling for a dealer, or anyone else, to adulterate milk with water, or that it is a matter of health to prevent any contamination whatever of milk. Not infrequently dealers and others make use of certain preservative salts to keep milk from souring in hot weather; such as borax, boracic and salicylic acids. These are irritating to the kidneys, and should never be used. The physician should exercise the utmost care as to the source of milk to be given to invalids and children, and he should make a personal inspection, if possible, of the cows furnishing them milk, and the manner in which they are treated and fed.

So much has been written of late concerning unwholesome meat that we may pass over the remarks on this subject. It is in the matter of sugar confectionery and jellies that the adulterator becomes an artist. Candies are adulterated to lessen the cost of the manufacture, as may be supposed, by the addition of substances which will diminish the strength without altering its appearance. The articles used for this purpose are terra alba, kaolin, starch, finely ground marble-dust, and pulverized asbestos. Adulterations in sugar confectionery are also used to improve the appearance, the coloring matters most frequently used being chrome yellow (lead chromates), Brunswick green (a mixture of chrome yellow and Prussian blue), red lead, Paris green, arsenical aniline, burnt umber, Venetian red (earths) vermilion (bisulphuret of mercury), and Prussian blue. After this the flavors are to be considered, these being made by distilling certain chemical salts with alcohol and sulphuric acid. One that is especially agreeable is

said to be obtained by treating rotten cheese with sulphuric acid and bichromate of potash. Much of the celebrated "rock and rye" and "rock and rye drops" is made of a preparation of sugar and fusel oil. "A most plausible current jelly, sold until a year ago by nearly every grocer and fruiterer, was made as follows: Dried apples, glucose, water, arsenical fuchsin (a red aniline pigment), tartaric acid, and glue. This mixture was boiled, strained, and sufficient salicylic acid added to keep it from spoiling in hot weather." There are very few of the fruit jellies sold now which are not frauds, though many of them are not dangerous to health. The apple does duty for almost every fruit, the other ingredients being glucose, water, color flavors, and gelatine.

With proper care in selecting canned fruit and vegetables there need be no danger unless the cans themselves are made of improper materials. Coffee and tea are adulterated. Almost all green teas are artificially colored; usually with Prussian blue, turmeric, or soapstone. Mustard is adulterated with terra alba and wheat flour, and then colored with turmeric, or a poisonous coal-tar preparation known as Marsh's yellow. Vermicelli is sometimes colored with chromate of lead, instead of eggs or saffron. The notorious "egg powder" is a new name for chrome yellow or lead chromate. Even oleomargarine has been adulterated by the addition of gelatine to make it absorb water, and we can scarcely doubt that impure fats are used in its manufacture.

As regards our foods, then, there are two sources of danger: Accidental contamination, and wilful adulteration. To remedy the first much may be done by educating the public in sanitary science, in Hygiene, the rudiments of which should be taught in every public and private school, and the further principles studied in the higher schools and colleges. In this way the people will be brought to know that the second danger may be averted and avoided by laws defining adulterations and fixing punishments for offenders; and by the appointment of efficient boards of health to carry out the laws; for laws cannot enforce themselves.

DR. FRANK HASTINGS HAMILTON.

In the death of DR. HAMILTON, which took place on Wednesday, August 11, surgery loses one of its masters, and American medicine one of its greatest lights. About two years ago he was attacked with pulmonary hæmorrhages, but on account of a vigorous constitution he safely weathered that storm. Since that time, however, his health has gradually

broken, and about three weeks ago he began to decline rapidly. He was born on September 10, 1813, in Wilmington, Vermont, and was therefore in the seventy-third year of his age. He was graduated from the University of Pennsylvania in 1833, having been a member of the medical profession for fifty-three years at the time of his death.

Since 1840 Dr. Hamilton has been known as a surgeon. Previous to 1844, when he removed to Buffalo, N. Y., he was Professor of Surgery in the Fairfield, N. Y., Medical School (1838), and a year later he was elected to the same chair in the Geneva, N. Y., Medical College, which position he held for almost four years. When he removed to Buffalo, in 1844, he became associated with the late Dr. Flint, and two years later they, with Dr. James Platt White, added a medical department to the University of Buffalo. Here Dr. Hamilton was Professor of Surgery for fourteen years, and in 1860 he removed to Brooklyn, where he was elected to the chair of Surgery in the Long Island College Hospital. He entered the Army as a surgeon in the early part of the Civil War, and was successively promoted to the ranks of Brigade-Surgeon and Medical Inspector of the U. S. Army. He was one of the founders of Bellevue Hospital Medical College, and occupied the chair of Surgery in it until 1875, when he resigned it.

Dr. Hamilton has contributed a very great deal to practical surgery and to surgical literature. His bone drill, apparatus for fractured jaw, compound Nélaton's probe, bullet forceps, bone forceps, serrated bone cutter, modified Liston's artery forceps, apparatus for double varus, hare-lip scissors, modification of Owen's tonsillotome, and his improvements and inventions in splints for fractures of the long bones are familiar to all surgeons. To him we are indebted for the use of gutta percha as splints, for the method of closing ulcers by transplantation of skin flaps, for a safe method of cutting the sternal portion of the sterno-mastoid muscle, for the operation of resection of hallux valgus, and for the generally accepted views concerning resection in compound dislocations of long bones. In plastic surgery he has contributed much; a method of operating from the forehead by turning the pedicle, and he was the first to operate from the palm of the hand.

In surgical literature his greatest works are his "Fractures and Dislocations," which is now in the seventh edition, and which has been translated into French and German; his "Treatise on the Principles and Practice of Surgery," first issued in 1872, and now in the third edition; his "Prognosis in Frac-

tures;" "New Views on Provisional Callus," and a "Treatise on Military Surgery." Besides these he has from time to time contributed valuable articles to current medical literature. It will be remembered that he was one of the consulting surgeons in the case of President Garfield, at the special request of Mrs. Garfield; and that he was instrumental in having the valuable aid of Dr. D. Hayes Agnew. The public has probably forgotten the outrageous treatment of these eminent surgeons by the committee to which was referred the Garfield claims; that people who were nurses or positively detrimental to the case were treated as well and better than they.

Even the enemies of Dr. Hamilton, if he had any, must deplore the loss to American medicine caused by his death. There are few in any country with so fertile a brain and so skilful a hand; so cool, deliberate and careful in speech, action and opinion.

THE PNEUMATIC CABINET.

The "Pneumatic Cabinet" has now been freely discussed in the journals for more than a year. Its physical principles have been set forth, its therapeutic value tested and endorsed by careful workers. That it is a real addition to our therapeutic armamentarium there seems to be sufficient evidence to show. It has not been vaunted as a cure-all for multiple and widely different affections, nor have any claims been put forward which bear absurdity upon their face. The owners of the instrument assure the profession that it will be kept out of the hands of quacks, and that persons desiring to rent it (for it is not for sale) must have the endorsement of the Advisory Board—and so far as can be seen they have endeavored to choose not only respectable but eminent men on this Board—men who can be trusted. Yet the machine does not seem to come into general use. Representative medical men in New York and other cities have, on consultation, advised the manufacturers to cover the Cabinet by patents *owned by the Company*, and it is rented under a contract which confines its control to the original lessee, and applications for its use are referred to an advisory medical board, without whose signatures of approval no application will be granted. The advertisement states that Cabinets are now in operation in New York, Brooklyn, Boston, Albany, Troy, Chicago, Cincinnati, Jacksonville, and other large cities.

The rental of the Cabinet is \$250 *per annum*. Let us estimate that each Cabinet costs the company \$500, which seems a high estimate. That is an income of 50 per cent. on the capital invested. The

lessee of the Cabinet has to pay too much for it, and so the Advisory Board should have pointed out. The high rental can effect nothing in the way of keeping it out of the hands of quacks and irresponsible parties, as that matter is in the hands of the Advisory Board. The Cabinet is practically out of the reach of men in small places; they cannot afford it, however necessary it may seem. And as a rule physicians, and people generally, are not partial to this method of doing business. No physician would wish to rent his pocket-case, his saddle-bags, hypodermatic syringe, speculum or obstetrical forceps, nor would he wish to pay the whole cost in two years' rental. As the case now stands only a very limited number of physicians can afford to have a Cabinet in the office. There is no good reason why a reputable physician should be denied the use of a Cabinet. It is a therapeutic agent, as is an electric battery. It requires no more tact or skill to use one intelligently than does an electric battery; but who would rent a \$100 battery at \$50 a year? If the owners of the Cabinet wish to keep it out of the hands of quacks by renting it let them reduce the rental. The medical profession will not willingly see any therapeutic agent of value limited to a few men. It by no means follows that a practitioner is incompetent to use a Cabinet because he cannot afford to rent one. The best locomotive engineer in Christendom may be unable to rent an engine for a month.

THE CHOLERA IN EUROPE.

The entire cholera mortality in Europe for four months and a half has been about 2,800, and there seems good reason to believe that it is dying out and will not spread to any considerable extent, though there is still time for further serious outbreaks before cold weather. A cablegram of August 16 states that the geographical area affected by cholera exhibits the capricious behavior of the disease. Thus, it is worse in Barletta, which is far away to the south, where the coast district between Monte Gargano and Brindisi is easily affected. Thence it makes a clear leap of 300 miles to Ravenna and Bologna, then turns northward, extending, though in a less virulent form, throughout Venetia, including the Island of Chioggia, and reaching as far east as Verona, and as far north as Castel Franco, at the foot of the Alps. It is a noteworthy fact that the places most seriously threatened lie in the centre or on the edge of marshy plains formed by the alluvial deposits of rivers or the silting of the sea, which always induce more or less malaria at this season of the year.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, August 2, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

OFFICIAL REPORT.

DR. L. L. MCARTHUR read a paper on

DIAGNOSIS AND TREATMENT OF HEPATIC ABSCESS.

Dr. McArthur divided the causes for abscess of the liver into intrinsic, or causes resident in the liver, and extrinsic, or causes external to and independent of the gland. To the former belong acute congestions, (said to result from heat and cold) tumors, echinococci, biliary calculi, or lumbrici in bile ducts. To the latter, infective emboli, whether carried through the portal vein or hepatic artery, traumatism, use of alcoholics in excess, high temperatures, surgical operations or lesions anywhere in tract of vena porta or its communications. All abscesses may be divided into idiopathic, infective or embolic and traumatic, in the order of their frequency respectively. First variety most frequently met with in tropics, and hitherto supposed to be due to high temperature irrespective of pathological conditions. Dr. McArthur believes them to be due generally to formation of biliary calculi. Most frequent abscess in this zone is the infective variety. Sources of infection are two: *Per arteriam hepaticum* and *per venam portæ*. First arise most frequently in pyæmia. Aseptic surgery has lessened the number of these cases. We can readily see how abscess of the liver may ensue by infecting particles reaching the liver when we remember all blood of the abdominal organs is returned to the general circulation via the liver. Hence, dysentery, ulcerations of the intestines, operations about anus and rectum, cystotomy, may cause abscess of the liver. Dysentery complicated the four cases he reported. The last variety of abscess, traumatic, comes from direct or indirect violence. The pain in abscess of the liver is severe according to the size of the abscess, its location in the liver, deeply seated or near the peritoneum, the amount of other tissues involved, lungs, stomach, pleura, etc., and its causation. When deeply seated may be symptoms only of "pus somewhere," chills, fever, sweating, etc., with general malaise. Locally, generally sense of weight and uneasiness on jolting. Tenderness variable, usually increase in hepatic area, and bulging of side. Temperature not often high, except when peritonitis; then present an important symptom, a peritoneal friction sound. This is hardly mentioned in literature, and yet is worthy of remembrance. Care should be taken to differentiate between pleurisy, or pneumonia of right lower lobe and hepatic abscess opening in this direction. Surgical interference by Volkmann's or Grave's method should be made as soon as possible. In the following cases two were operated upon and recovered; in the third the expectant treatment was followed and death ensued;

in the fourth case a diagnosis was not made because of absence of characteristic symptoms.

On concluding his paper Dr. McArthur gave the following verbal report of cases: The first case was a man, 35 years old, formerly strong and healthy, weighing 160 pounds, a roustabout. Family history good. Four years previous to coming under my observation, while in Louisiana, he had had hepatitis with enlarged liver, from malaria. He was engaged when taken in present illness in unloading a cargo of peaches. He ate freely of them, and an acute diarrhoea ensued, which became dysenteric in character. One week prior to admission to the hospital he complained of pain in the hepatic area. At the time of his admission his general nutrition was good, tem. 103, complained of tenderness in the hepatic area, had diarrhoea. On making an examination I found the hepatic area enlarged, with tenderness over it, slight redness of the integument over the right lobe of the liver. On completing the auscultation of the lungs I placed my stethoscope over the liver and heard a very distinct friction sound which characterized the invasion of the peritoneum by inflammation. Three days later a hypodermic syringe was introduced into the liver and pus, and a sero-purulent fluid withdrawn, and the diagnosis of abscess of the liver was completed. As soon as the friction sound had ceased, that is, when adhesion had taken place, an operation was performed by making an incision about two inches in length and carefully dividing the tissues until the peritoneum was reached and the adhesions found; when the abscess was opened, the contents evacuated and a drainage tube inserted. The man was discharged cured in the course of forty-two days. The second case was a man formerly in good health; family history good. He came to the hospital complaining of fever, disagreeable taste in the mouth, pain in the right shoulder and down the back. Normal heart and lung sounds, except on the right side, where their was evidence of commencing pneumonia in the right lower lobe. Marked enlargement of liver in the right hepatic area. In this case the attending physician advised the expectant treatment, hoping that the suspected abscess would open through the lungs, and a cure be effected in that way. In ten days the man died and a large abscess was found in the liver filled with normally appearing pus, complicated by circumscribed pneumonia and diaphragmatic pleurisy, showing the efforts of nature to get rid of the pus in a natural way. The third case was one in which the abscess was deeply situated in the liver substance. There was no local tenderness, no enlargement of the liver, only the sensation of pus somewhere, with rigors, fever, chills and sweating. There had also been a diarrhoea. He finally succumbed to blood poisoning. Post-mortem showed an abscess in liver. The fourth case was in St. Luke's Hospital, and was operated upon and recovered.

DR. FRANK BILLINGS upon invitation said: I probably have had less experience with living patients with abscess of the liver than any one present, and consequently have less that is practical to say about it. While in Vienna I saw a great number of autopsies of abscesses of the liver. Several cases occurred in the

wards, but no diagnosis of abscess was made, the patients suffering from what appeared to be intermittent fever, and usually a diagnosis of that kind was made. A curious thing to me was the fact that a great number of these abscesses were found in new born children. In Vienna, one often sees in the dead-house abscesses which were the result of badly attended cord. The pus had formed in the vein and the inflammation spread upward, finally producing abscess in the liver.

DR. H. A. JOHNSON said: While listening to this paper, a somewhat unusual case was recalled to my mind which occurred in the County Hospital when we were down on 18th street. This was a case of abscess in the left lobe of the liver which had communicated, evidently some time before death, with the left lung, and was discharged through the bronchus. When the case came into the hospital it presented all the signs of empyema, and the complication of the abscess with the liver was only discovered in the dead-house. Another case occurs to me in which there was abscess in the right lobe of the liver discharging through the right lung. The patient recovered, but five or six years after a recurrence of the abscess took place, and it discharged into the vena cava, producing instant death. Post-mortem revealed the cavity of the abscess communicating with the vena cava. Both of these cases seemed to me to be somewhat out of the history of abscesses.

DR. J. J. M. ANGEAR said: In all cases that I have seen the discharge had a fearful odor, and I began to think that if the pus did not have that odor, I should have doubts of its being an abscess of the liver.

DR. J. A. ROBISON said: I have just had in the County Hospital a case of abscess of the liver in which the diagnosis was made only after death. The remark of Dr. Billings, that abscess of the liver is often diagnosed as malaria, leads me to speak of it. The case was that of a woman who had been ill for several months. When I first saw her in the Hospital about a month ago, she was greatly emaciated, jaundiced, and complaining a great deal of pain in the hypogastric region. The liver was not enlarged, temperature ranged from 100 to 102, she had chills every few days, and it was supposed they were due to malaria. She finally died of exhaustion.

There was no diarrhoea, but there was great tenderness over the hypogastric region together with general jaundice. There was also a cachectic appearance which led me to believe there might be catarrhal inflammation of the duodenum which would account for the jaundice. But upon post-mortem examination it was found to be a case of multiple abscesses of the liver, with purulent inflammation of the gall ducts. I have in the hospital another case in which nearly all the signs that Dr. McArthur has spoken of here occurred. The patient is a woman about 40 years of age, in whom the area of liver dulness is greatly increased. Temperature 100, extremely jaundiced, and when she first came into the hospital I heard the friction sound as mentioned in the paper, but that has now disappeared. Since hearing this paper I am led to believe we will find a large abscess of the liver in this case.

DR. JOHN BARTLETT said: At the time of the Mexican War, many of the soldiers returned affected with chronic diarrhoea. In seven of these cases which came under my observation, enormous abscesses of the liver followed. They were not opened, but were particularly examined in the dead-room, some of them containing at least a gallon of pus. As a general rule the patients lived for months. About a year ago I was called to see a case in consultation. The man had been tread upon in a crowd and received a slight injury about the epigastrium. Inflammation followed and abscess of the liver was diagnosed, but owing to a difference of opinion among the consultants no effort was made even to aspirate. After death, which followed in due course, multiple abscesses were found, one as large as a small cocoanut, another as large as an orange, and fifty other smaller ones. I mention this to prove how hopeless would have been an attempt to improve the condition of this man by aspiration. I saw another case of some interest: The man was shot and some weeks afterward died. I opened the body and found a piece of wadding and the bullet in the liver. The abscess was about as large as two fists and opened into the vena porta. In another case I was called in consultation to see a man who appeared to have an affection of the liver. Both of the attending physicians thought it was a case of abscess. Presently he had symptoms indicating that there was some difficulty in the respiratory organs, and later, but in time to act if we had been more prompt, we discovered that there was a retro-pharyngeal abscess. I immediately expressed the opinion that the abscess in the liver had opened into the anterior mediastinum. I deemed it inexpedient to open this abscess without having other instruments than we had with us. We went to get these, and when we returned we were advised at the gate that the man had been taken with a difficulty of breathing which simulated croup and had immediately expired. Upon examination we found that he had been drowned, as it were, by the pus from the bursting of this large abscess.

DR. H. N. MOYER asked Dr. McArthur if in the literature on the subject he had seen anything in reference to the presence of acetone in these cases? Jaffey has laid down indications of diagnostic value when this substance is formed. He thought the symptoms might lead to the development of this substance in the urine, and that it might be of some diagnostic value, in suspected cases of abscess of the liver.

DR. L. L. MCARTHUR said, in closing the discussion, I was interested to learn of another source of abscess of the liver to be by infection from the umbilical cord as related by Dr. Billings. Dr. Johnson's case of abscess of the liver breaking into the left pleura and left lung is the only one I have known of. Rupture into the vena cava is also rare. To Dr. Angear I would say that in the cases I saw the discharge was odorless, and I emphasized that fact in the paper because the books all state that as a rule it possesses a very offensive odor, and is usually of a purulent character. In two of the cases I saw it was of a chocolate color being mixed with blood and liver-

tissue. Dr. Robison speaks of a case as markedly jaundiced. This is set down as an exceedingly rare complication in abscess of the liver. He said that in his case the liver was found in post-mortem to contain multiple abscesses, I would like to ask if the cause was found? (Dr. Robison: We found no cause.) I would ask Dr. Bartlett if his case proved to be a case of abscess of liver with a mediastinal opening? (Dr. Bartlett: We presumed it to be hepatic, but no post-mortem was allowed). As to acetone, I have seen no literature on the subject in connection with the liver. In those cases in which I used the hypodermic needle to make a diagnosis (three in number) two were operated on and recovered, the third was treated by the expectant treatment and died. No careful search was made for the puncture of the needle in the abscess of the liver. After the first two cases I became bold in the use of the hypodermic needle and punctured for the fourth time in one case before I obtained purulent matter.

DR. SCOTT HELM read a paper entitled

A SUBCUTANEOUS METHOD OF THE TREATMENT OF BUBOES, WITH EXHIBITION OF THE INJECTING INSTRUMENT.

His method consists in injecting the suppurating gland, after the pus is withdrawn, with a solution of carbolic acid to wash out the cavity, and then injecting and allowing to remain an emulsion of iodol in pure oleic acid. The injecting instrument consists of a barrel holding two drams, which is mounted on either side by two rings for the fore and middle fingers, and a ring in the end of the piston for the thumb. Three needles, two different sizes of aspirator needles, and one a canula with trocar. To these is attached the centre joint, in which is a stopcock, the opposite extremity of which is attached by a smooth joint to the barrel. In twenty-three cases the treatment was successful in all but the nineteenth, this patient having gone on a protracted spree following the operation. The advantages of the operation are that when there are two or more suppurating buboes in the same chain of lymphatics, the second or third appear further away from the initial one; by placing the first glandular abscess in a perfectly aseptic condition you prevent the inflammations of neighboring glands; secondly, there is no cicatrix remaining.

DR. J. ZEISLER: If conservative surgery has any place I think it is in the treatment of buboes, and I think the final bad result of treating buboes by section might be avoided by carrying out the idea of Dr. Helm. It is a good idea to inject iodol as it may be regarded as a specific against the venereal poisons, and there can be hardly a doubt that the suppuration is due generally to the poisons. I would like to know if the doctor has found it sufficient to introduce this iodol emulsion more than once?

DR. G. C. PAOLI said: In the treatment of buboes of course the sooner we get out the pus the better, but those who have had experience with the treatment of buboes know that there are cases in which, in spite of aspirations and subcutaneous injections there is still a morbid process going on which produces mischief and ulcerations of the tissues. I never

use carbolic acid, but I have used a watery solution of permanganate of potash, $\frac{1}{2}$ gr. to 6 ounces, injecting it into the cavity. But we all know that we have cases of buboes which in spite of all the skill of the physician produce the greatest suffering. I saw a case where the femoral artery had to be ligated. In temperate persons we have very tedious buboes. Again, where mercury has been used too freely there are often mischievous buboes. Very difficult cases are those in business men who are busy, active, and produce more congestion of the abscesses by their activity. But if we can get the patient to go to bed and rest we succeed better in our treatment. However, I think favorably of the subcutaneous method.

DR. FRANK asked Dr. Helm how many of these buboes were due to gonorrhœa and how many to chancres or chancroids, if any?

DR. H. N. PIERCE said: I had the pleasure of seeing Agnew, Jr., four years ago experiment with the subcutaneous treatment of buboes. He first evacuated the pus by use of the canula, then injected an antiseptic solution, washing it out and afterwards applying a compress bandage. The buboes generally went on from bad to worse, and he tried the same method over again but with no success, and finally he had to cut down upon them and treat them by the old method.

DR. SCOTT HELM in closing the discussion said: I have made, in any case, only one injection, and the time that has elapsed before the patient was discharged has been from eight to fourteen days. In reply to Dr. Feder I would say that these buboes have been aspirated as early as possible, as soon as there was fluctuation. All the pus was removed and the cavity injected with a like quantity of the oleic acid emulsion of iodoform. I have had no case in which there has been a return of the disease in the same chain of glands. I had one case in which there was a bubo appeared some two weeks afterward in the opposite groin, evidently due to gonorrhœa. In the second case, and the last one, which only occurred a few days ago and was not reported, the buboes were caused by gonorrhœa, all the others were due to chancroids.

IN MEMORIAM.

Mr. President: Since our last meeting it has pleased Divine Providence to call from our midst Dr. Robert C. Hamill. The Committee on Necrology respectfully submit the following resolutions:

Resolved, that this Society has learned with profound sorrow of the death of Dr. Hamill, one of the earlier as well as one of the most earnest and efficient members of this Society.

Resolved, that in the death of Dr. Hamill this Society has lost a member typical of the true gentleman in the kindness of his manner, in the great force and energy of his character; typical of the good citizen in his ceaseless efforts to advance the interests of institutions tending to ameliorate the condition of the sick and unfortunate; typical of the patriot in his unceasing efforts to aid and cherish the disabled soldiery of his country; typical of the wise counsellor in the soundness of his judgments; typical of the

true physician in his earnest cultivation of medical knowledge and in his philanthropic practice of the healing art; typical of the faithful Christian in his never flagging zeal in all good works.

Resolved, that the Society extend to the bereaved widow of the deceased in her great loss, sympathy and condolence.

JOHN BARTLETT,
CHAS. GILMAN SMITH,
H. A. JOHNSON
Committee on Necrology.

CHICAGO GYNÆCOLOGICAL SOCIETY.

*Forty-Seventh Regular Meeting, Friday Evening,
May 28, 1886.*

THE PRESIDENT, DANIEL T. NELSON, M.D., IN
THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

(Concluded from page 191.)

The PRESIDENT exhibited specimens removed from

A CASE OF SUPERNUMERARY DIGITS.

While I know the condition is not exceedingly rare, I thought the specimen was so beautiful as to be worthy of presentation to the Society. The specimen consists simply of two supernumerary little fingers, which I found in a beautiful, healthy baby just after it was born, attached by small pedicles, consisting simply of the skin and the vessels needed to supply them, about the middle of the first phalanx of the little finger; the pedicles were perhaps one-sixteenth of an inch in length, just long enough to ligature. They look like little beans; the finger nails are fairly developed in both. They were very vascular. They looked, before removal, like bangles. This was the sixth pregnancy; the other children were all perfect; no other case of this condition in the family that is known. The condition is usually hereditary. In one there is a very good nail formed, upon the other there is only a slight nail. The mother is in good vigor and health. They were united to the larger little finger about the middle of the first phalanx—one was just about the middle of the phalanx, on the outer border; the other half way between the middle line and the outer border. They both feel as if there are bones in them—two phalanges in each, the third being represented by the pedicle.

DR. CHARLES T. PARKES, (Rush Medical College, 1868,) read a paper entitled

UTERINE FIBROIDS TREATED BY THE FLUID EXTRACT OF ERGOT.

My intention is to relate to you the history of four cases of uterine tumor, and to present a few remarks suggested by them. These four cases were treated by the internal administration of Squibb's fluid extract of ergot. They all resulted in recovery by expulsion of the growth.

I found no insurmountable difficulty in giving the

medicine, although when given for a prolonged period it creates nausea and disgust in some. This was counteracted, and the pain following its use controlled by combining it with morphine. It seemed to me preferable to the hypodermatic use—the latter being locally painful and often producing abscess, besides it is not followed by any better result. Two of the cases, treated by ergot, when thrown off, proved to be pure uterine fibroma—dense and hard—white and glistening when cut open—consisting of simple fibrous tissue. The other two following the action of ergot were soft myomata—pultaceous and semi-elastic—consisting mostly of connective tissue, confirming the diagnosis made. All four of these were evidently submucous tumors, or so slightly interstitial as to be practically covered only by mucous membrane.

CASE I.—Mrs. S., American, 43 years old, widow, three children, no miscarriages, menstruated first when 16 years old. Never had any noticeable trouble with menstruation until three years previous to my first examination; during these years she had suffered with irregular profuse hæmorrhages which were now continuous, accompanied with exacerbations on the slightest exertion. My first examination was made February 20th, 1876. As my memory brings this patient before me she presented the most perfect example of transparent flesh that I had ever seen. A large, finely formed woman, her flesh looked like alabaster, apparently destitute of blood. The legs were œdematous, the heart beat feeble and rapid, and the slightest exertion was followed by extreme palpitation and the most fearful feelings of suffocation. Her answer as to what she had done for her trouble was that she had taken "quarts of medicine." Vaginal examination revealed an enlarged uterus and patulous os, from which blood was rather freely oozing. The sound entered the uterus about five inches, the handle being deviated forwards and to the left side. A diagnosis of submucous uterine fibroid was made.

The treatment adopted was the administration of strychnia and iron, together with wine and good diet for the general condition, and one-half drachm doses Squibb's fluid extract of ergot every six hours, to either expel or kill the growth. Locally, to stay the hæmorrhage, a small tampon of pulverized alum was applied to the os uteri and held in position by ordinary cotton tampons.

The first forty-eight hours' use of the ergot produced quite serious uterine pains, so acute that the patient in her weakened condition said they were unbearable. At this visit Professor T. D. Fitch was with me in consultation. The tampon of alum was removed, and Dr. Fitch's examination confirmed the diagnosis made, and advised the continuation of the treatment. As the bleeding had been entirely controlled by the tamponade, it was left out. The ergot was continued as before, and a sufficient dosage of morphine ordered, to make the pains bearable if they persisted. No further use of the tampon was required, the uterine contractions never ceased while the ergot was administered. On the sixth day of its use a foul-smelling serous discharge came on *per vagi*.

nam, accompanied with slight general chilliness, and a temperature of 102° F. The patient was assured that the tumor was surely coming away, and encouraged to bear "yet awhile" with her great suffering. On the eighth day the tumor was found in the vagina and removed. It was about the size of a duck's egg and very hard to the touch. After a short period of mild septic trouble the patient passed through a quick convalescence and rapidly recovered. Save a few months ago she says she has never had any illness since getting rid of this growth, and certainly looks well.

CASE II.—Mrs. P., German, married, five children, no miscarriages, menstruation began at 14, now 37 years old. Seen by myself first in March, 1881. The patient is a robust, hearty woman. Never had any trouble until six months after the birth of last child, about one year ago, when she began to flow too freely and too often—as often as every week or occasionally twice a week. The blood was in large quantity and bright red in color.

The examination revealed an enlarged uterus—it could be felt above the pubis during bimanual examination. The sound entered easily for five inches, the handle deviating forward and to the left. Its use was accompanied and followed by very free bleeding.

Diagnosis.—Submucous uterine fibroid on anterior wall. *Treatment.*—Locally the alum tampon was used as in the previous case. Squibb's fluid extract of ergot in half-drachm doses every six hours. The patient was ordered to remain in bed. On the succeeding day all the tampon, except the alum, was removed. No hæmorrhage; slight pains complained of. On the second day the pains were very severe and morphine was given to control them. The alum tampon was removed and a carbolized hot water injection ordered three times a day. On the third day pains still severe and a foul-smelling vaginal discharge commencing.

This condition persisted until during the night of the eighth day, when I was summoned to the patient on account of the unusual severity of her sufferings, the messenger, her husband, saying it was just as if she were having a baby. On my arrival the pains had quite ceased. Examination showed the loss of considerable blood, and the vagina was found filled with a large fleshy mass, horribly offensive. The finger could be passed beyond it, and the largely opened cervix recognized. It was seized with a Vulsellum forceps, twisted a few times upon itself, and then delivered. The mass was as large as a closed fist, dark colored and ragged all over its surface and very foul-smelling. The patient rapidly regained her usual health, and is well to-day.

CASE III.—Mrs. E., 33 years old, married, three children living, one miscarriage, menstruation commenced when 14 years of age. Was first called to visit her January 2, 1885, for severe uterine hæmorrhage. She then informed me that she never had any menstrual trouble until about two years previous.

Shortly thereafter she was operated upon for laceration of the cervix, without much relief to her trouble, since she had gradually grown worse, so that she was not free from bleeding ten days in the month.

One year previous to my seeing her, the uterus was freely curetted and fuming nitric acid applied to the cavity as a relief to the bleeding. The procedure failed in any good result.

At this visit the bleeding was extreme in degree. Examination revealed the pelvis largely filled with a smooth, doughy mass. After considerable searching the *os uteri* was found high up above and close to the pubis. It could only be found by crowding the finger between the bone and the growth. The growth was exquisitely tender to the touch or any manipulation. Bimanual palpation discovered an uncertain mass above the pubis. The vagina was tamponed temporarily, and morphine administered hypodermatically. The diagnosis was reserved. In my mind it rested between hæmatocoele and soft myoma. The tumor was compressible, at least its elements seemed to give way to the pressure of the finger; it was semi-elastic and painful under manipulation, filled the entire posterior half of the pelvis, and the *os* was carried well upward and forward. It might be and probably was, a myoma of the posterior uterine wall retroverted.

A few weeks ago I had the satisfaction of seeing the *fac simile* of this case, so far as the character of displacement and the position of the tumor was concerned, in a patient under the care of Dr. Merriman, although the tumor in Dr. Merriman's case was much harder and more resistant.

Dr. Merriman, with skill and apparently with ease, lifted the tumor out of the pelvis into the general abdominal cavity, after placing the woman in the knee-elbow position—a change bringing much comfort to the patient. I learn that under the use of ergot the growth is already diminishing in size.

The patient was put upon fluid extract of ergot in one-half drachm doses three times a day. The next menstrual period showed no change other than a diminished loss of blood. In June the flooding was quite free and accompanied with considerable pain. In July everything was as bad as possible, with so much pain that the ergot was discontinued. Repeated examination now narrowed the diagnosis down to soft myoma. The removal of the uterine appendages was suggested, in the hope that this procedure would anticipate the menopause, stop the bleeding, and lead to the gradual atrophy of the growth. In September, consultation was solicited with Professor W. H. Byford, when the patient was etherized and carefully examined. The sound, introduced with great difficulty, owing to the displaced position of the *os*, passed in over five inches, positively demonstrating the nature of the growth, its consistency showing it to be the soft variety of myoma.

As the patient could not be said to be in absolute danger of her life, the operation was refused by her friends, although the sufferer was willing enough to have it done. The previous treatment was endorsed by Professor Byford, and its continuance advised. The fluid extract of ergot was resumed and rendered bearable by morphine.

The October illness was accompanied by slight hæmorrhage, but excessive pain. The uterine contractions continued on after the menstruation ceased,

until during the last week of October, they became labor-like in character. Examination now revealed that the uterus had righted itself, the os was becoming patulous and its edges thinned out; through its opening the projecting tumor could be felt. On the second day of November, pieces of the broken-down mass, horribly offensive, could be seized with the forceps, pulled out of the uterus and cut away.

Chilly sensations began to be felt by the patient, sweating came on, the temperature ran up to 101° F., and a mild septicæmia was established. During the following week the pains never ceased. Quinia was administered freely. The vagina and uterus were irrigated with hot carbolized injections, and the mass removed as fast as any of it, could be reached, and at the week's end the last remnant was gotten away. The patient was very much reduced physically, but rapidly convalesced, and is now perfectly well, with her menstruation normally reestablished. Fully a quart of soft pulaceous pieces of the growth were removed.

CASE IV.—Mrs. L., German, 34 years old, one child, was seen first November 1885. She had been suffering with increased menstrual flow for a year. She came to me to be treated for an external, painful, labial swelling. It proved to be a vulvo-vaginal abscess. It was opened freely and gave no further trouble. A uterine tumor was noticed and examined. It was found to be of considerable size—could be detected above the pubis.

She was put upon one-half drachm doses of fluid extract of ergot every six hours.

This she continued for six months steadily, with varying conditions of pain and hæmorrhage, until in April, 1886, the hæmorrhage ceased, pain became very severe, and a shreddy, foul-smelling discharge manifested itself. She was removed to the St. Joseph's Hospital, and after ten days of antiseptic washings and removal of masses of broken-down tissue, the mass was entirely extruded. This patient had also quite a severe septicæmia, but finally recovered and is now well.

Remarks.—Aside from crucial demonstration, it seems reasonable to assert that these four cases were cured by means of the remedy used, and by that alone. It is well known that the most of authorities state that no positive reliance can be placed on the use of ergôt. My experience, surely, as here illustrated, and confirmed by other cases seen, leads me to think that this adverse judgment must be qualified, especially in the treatment of the submucous bleeding fibroids of the uterus. If the growths be partially interstitial, the less the thickness of uterine tissue between them and the mucous covering, the more certain will the remedy be curative. Of course it will be impossible to demonstrate the exact amount of uterine wall forced contractions will destroy, hence a trial of its worth is desirable in all cases not purely sub-peritoneal and pedunculated. Still I am quite convinced the severity of the hæmorrhage gives one a good reason to speak *positively* of the results to be accomplished by its use. I have not deemed it necessary to look up the history of the first use of this remedy for stimulating

uterine contractions. It is sufficient for me to say that my confidence in the remedy and persistence in its use, even when failure of good results seemed certain, has followed directly as the result of the teachings and experience of an honored Fellow of this Society, Professor Wm. H. Byford, who has never lost an opportunity to urge upon the profession his belief in the specific action of the remedy, and its absolute certainty of cure in many cases. I am quite sure that Professor Byford deserves the credit of being the first to make use of ergot with the idea of destroying the vitality of the growth, and as well, causing its expulsion from the uterus.

The third case shows plainly how absolutely unnecessary any operation would have been. The removal of the appendages might have stopped the hæmorrhage, but such a perfect cure as now exists could never have followed operation, to say nothing of the harm done by unsexing the woman; still no case could present better reasons for such a procedure, none in which it would have been more justifiable from the indications present. To me it brings the lesson to make oöphorectomy the *dernier ressort* in all cases, certainly to give the remedy used at least a six months' trial without result before operation be sanctioned.

The difficulties attending the differentiation between a sack of fluid and the soft myomata was well illustrated by this case. The sensation communicated to the touch was scarcely distinguishable from fluctuation. It was only after repeated examinations under ether, and the use of the sound, that the diagnosis was satisfactorily settled.

The fourth case for a time seemed one in which the treatment would come to nothing. Every one became discouraged. The suffering was increased, and no advance was made, apparently. By persistence the cure was accomplished. In this case operative interference was solicited by the patient, and would have been most readily submitted to, without any urging. If I read aright the indications which authorities give to justify the resort to removal of the uterine appendages, they were all present in this case, and more too if that were needed. Certainly the final result has proven that any such interference would have been uncalled for and lamentable.

I am quite well aware that four cases cannot be considered absolutely demonstrative of any rule; still these four increase the number already published in proof of the curative action of ergot, administered thoroughly, for submucous uterine growths. It is impossible for me to understand how some good authorities can still assert their disbelief in ergot; in fact, calling it the most inert and disappointing of all drugs. No possible argument can disabuse my mind of the belief that its action was positive and certain in the cases related. No law has yet been evolved fixing even by approximation the period of time required for the effects of the medicine to show themselves. The idiosyncrasies of the patient, the thickness of the uterine envelope, the distance from the mucous membrane, the purity of the drug, and many other conditions, render it scarcely possible that any

such law can ever be laid down. The trial should be made patiently and persistently, just so long as the patient's condition will warrant its continuance, and a complete expulsion of the growth, followed by rapid recovery, will be the reward.

DR. F. E. WAXHAM read the following paper, entitled:

OCCLUSION OF THE OS UTERI AS AN IMPEDIMENT TO LABOR, WITH A REPORT OF TWO CASES.

Having met with occlusion of the os but once in several hundred cases of labor, and knowing of a number of physicians of extensive practice who have never seen this condition present at the time of confinement, I am convinced that it must be of rare occurrence, and the history of two cases may not be uninteresting.

Mrs. S., primipara, 29 years old, German, fell in labor about 9 P.M., February 21, 1885. The membranes ruptured soon after the commencement of labor and the amniotic fluid gradually drained away.

The patient was seen between 3 and 4 A.M., at which time the pains had become very severe and frequent. Upon examination the head was found low down in the inferior strait, almost presenting at the vulva, and covered apparently by a thin membrane through which the advancing head threatened to burst with every pain. Upon the most careful digital examination no os could be discovered, nor the slightest indication of one. Professor Nelson was summoned and promptly responded. His more experienced finger detected a very slight dimple in the centre of the presenting tissues. By keeping the finger upon this slightly thickened tissue, he discovered that it became very much thinner with every pain, while as the pain subsided the tissue assumed a very slightly umbilicated appearance. By firm and continued pressure upon this suspicious spot an opening was at length effected and the os gradually dilated. As the labor proceeded slowly, and fearing the result to the child of so long a delay of the head in the pelvis, and the os being fully dilated, the forceps were applied. The child was delivered without injury to the mother, but it was asphyxiated and required considerable effort in resuscitation. Professor Nelson stated that this was the second case that had ever come under his observation, and kindly gave me the history of the following one: He was called to attend a lady in her first confinement, a Swede, 23 years old, and married about one year. Making a hasty examination, he found a well-formed cervix but did not detect the os. On returning a few hours later, the head had descended to the inferior strait and was indeed presenting at the vulva and covered by the cervix, which had become so thin as to resemble the membranes. The membranes had already ruptured and the amniotic fluid had gradually escaped. There was no appearance whatever of the os. It could not be detected with the finger, and the head seemed about to burst through the uterine tissue. The patient was placed before a window, the labia separated and careful search made for the os. Only after a most careful search was it found. It was patulous only to the extent of admitting the very

finest surgeon's probe. After this had been introduced and worked about a second probe was passed, and by separating them the os was gradually and sufficiently dilated to allow the finger to enter. The os was then rapidly dilated and labor progressed normally.

I find the literature on this subject quite meagre, many of our writers on obstetrics omitting the subject entirely, while others refer to it very briefly.

Schroeder alludes to it in the following terms:

"As complete atresia of the os prevents conception, it follows that an occlusion of the os, observed in labor, must have taken place during pregnancy.

"Very frequently there is a superficial and easily separable agglutination of the external os. It is due to an inflammatory process of the lips of the os from a previous blenorrhœa. During labor the advancing head is seen to push the lower uterine segment forward to the outlet, and to thin it more and more. This thinning may be so great that the head appears to be covered only by the membranes. By an accurate examination the os feels like a small and soft dimple directed greatly backwards. If during a pain the finger or uterine sound be forcibly pressed against the dimple, the agglutination of the os will suddenly give way. The os itself now very rapidly dilates and labor proceeds without impediment. Often the pains themselves succeed in breaking down the adhesions of the os.

"It very rarely happens that the os only partially dilates after the agglutination has been torn through and remains rigid so as to later require incisions. There is very seldom so firm an adhesion between the maternal and foetal membranes in the immediate vicinity of the internal os that the lower uterine segment cannot retract over the ovum. Separation by the finger or rupture of the membranes renders possible the dilation of the os."

Schroeder also refers to the fact that a firm cicatricial band may occasionally occlude the os, resulting from inflammation of the cervix or cauterization:

"When these firm adhesive bands prevent dilatation of the os there is danger of rupture of the vault of the vagina unless incisions are made and assistance given. The cicatricial closure of the os is frequently incomplete; more or less fine openings remaining pervious, rendering conception difficult but still possible, is believed by Schroeder to frequently result from ulcerative inflammation during the lying-in state."

Leishman, in discussing this subject, remarks that

"There are some cases in which there seems to be actual occlusion of the os. Impregnation in the case of an absolutely occluded os is as impossible as that the normal function of menstruation should be carried on, and therefore we must assume, in such cases, that the closure must have taken place subsequently to the entrance of the seminal fluid. It is of course possible that the os may remain open to a very limited extent, and yet the state of the tissues renders distension impossible, so as to practically constitute an impediment as insurmountable as actual occlusion would be."

Playfair mentions this condition as follows:

"Agglutination of the margin of the os uteri is occasionally met with and must of course occurred after conception. It is generally the result of some inflammatory affection of the cervix during the early months of pregnancy. Usually it is not associated with any rigidity or hardness, but the entire cervix is stretched over the presenting part and forms a smooth covering in which the os exists only as a small dimple, and may be very difficult to detect at all. Occlusion of the os from inflammatory changes sometimes so alters the cervix that no sign of the original opening can be discovered."

All our authorities agree that the occlusion of the os is the result of inflammatory change occurring subsequent to impregnation. It is a noteworthy fact that in both these cases the membranes ruptured and the amniotic fluid escaped in the very early stages of labor, showing that the membranes were adherent to the uterine tissue about the internal os. As the internal os dilated, rupture of the adhesions and of the membranes necessarily followed.

The discussion of the papers read by Drs. Parkes and Waxham was, on motion, deferred until the June meeting.

Mr. Lawson Tait, of Birmingham, and Dr. T. Gailard Thomas, of New York, were elected Honorary Fellows of the Society.

Dr. E. C. Dudley proposed for honorary fellowship Protheroe Smith, M.D., M.R.C.P., of London.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, April 21, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

DR. J. TABER JOHNSON presented a

CYST OF THE BROAD LIGAMENT,

which he had removed that day. The following is a brief history of the case:

Mrs. T., white, a widow, never pregnant, aged 32, first noticed that she had a tumor growing low down in her left side, last June, just eleven months ago. It gave her considerable pain, especially in her bladder, and caused her to pass water frequently. She began to be irregular in her periods, missing at one time as many as four months. Her appetite and digestion became impaired, and she lost flesh rapidly. She became nervous and apprehensive, and lost much sleep. Her face was thin, careworn, and presented the characteristic "facies ovariana" to a marked degree.

She was sent to him by Dr. N. S. Lincoln. She presented the appearance of a woman eight months pregnant. Upon examination Dr. Johnson diagnosed a cystic tumor, and said it was probably ovarian, but declined to say positively until after the operation, which he advised should be made at once.

Dr. Lincoln and the patient agreeing with this view, he appointed the next Wednesday for the operation. As Mrs. T. declined to go to an hospital, her house was made as aseptic as possible, and the

tumor was removed on the April 21, with the assistance of Drs. Cutts, Brownell, and Cuthbert.

Dr. Lincoln was present and kindly approved of the various steps of the operation. The cyst and its contents weighed eight pounds. After being emptied of its contents it was removed through an incision not more than three inches in length. There were no adhesions; the pedicle was unusually broad; it was transfixed and tied in two divisions, and burned off with the thermo-cautery. The ovary was found to lie upon the surface of the cyst, and was attached to it by a broad membranous band.

P. S. May 5.—The patient is doing well; the wound healed by first intention, and she is sitting up.

In accordance with the resolution requesting CAPTAIN SYMONS, U. S. A., to present his

METHOD OF FILTERING THE CITY WATER SUPPLY,

passed at the last meeting, the Captain kindly appeared before the Society and read a paper, of which the following is an abstract: He said that complaints of the condition of the water were frequent, especially among the new-comers to the city. On investigation he found that physicians considered it unwholesome for invalids and children, the temperance people thought it was a stumbling-block to their cause, and that the people in general, when it was at its worst, were alarmed lest it be the cause of some epidemic. Moreover, the expenses of house filtering and boiling the water, as was frequently done, was an unnecessary tax on the people. Domestic filtration at best only half reached the desired end, and these filters might easily become the foci of disease from the decay of accumulated filtrates. Many different analyses of the water showed a varying amount of organic impurities, but all samples contained more than there should be in a water of the highest excellence. In 1882 three chemists examined the water. Two reported it as of "medium purity," and one as "good." The biological examination, made under the same auspices, showed it as "doubtful."

Comparison with the London and Berlin supply showed our water to contain fewer impurities than did the waters of those cities at their sources, but more than was in them after they had been filtered for use. A circular letter which he had addressed to the physicians of the city had elicited the reply that the water was unsatisfactory and needed purification. In view of these facts, he had undertaken an investigation with the hope of solving the difficulty, and of giving the city a cheap and efficient method of filtering its water before delivery. The drainage area of the Potomac above the point where it is tapped for this city is about 12,000 square miles. There are several, at present, small towns in this area which pass their sewage into the river. The lands are highly cultivated and every year more fertilizers are being used, forests are being cut down, and thus increasing sources of pollution are constantly arising. These it will soon be necessary to check, as have already some of the European cities. He then went on to say that there were three ways usually applicable for the filtration of the quantity of water necessary for

a city, namely: *Large subsidence reservoirs, natural infiltration* into galleries built along the margin of or in or under a river, and *artificial filter beds*.

Clarification by subsidence, which was the only system of the three in use here, would not do well in a warm climate, for the water, which must of necessity remain in a quiescent state for three or four weeks, would become full of aquatic life and fungi. This was the cause of our alarm last summer. The natural filtration, which is applicable *only* where large deposits of sand or gravel are found in a convenient position along the water supply, is probably the cheapest and best. In this large chambers or wells are dug, and when full of water percolated from the river or lake are emptied of their contents for use.

Artificial filter beds consist of tight masonry basins with drains along their bottoms radiating to the outlet. First is put in a layer of coarse gravel, then a layer of finer gravel, and finally the true filter, about five feet of fine sand. The river water is then run through these layers and conveyed to a large reservoir for distribution. The first cost of such a system would be tremendous, as about twelve acres of such beds would be necessary to keep this city supplied. It is also very difficult and expensive keeping them clean.

It is estimated that the city at present uses from twenty-five to thirty million gallons daily. With the new tunnel there will be about thirty-five million gallons supplied daily. Eventually from thirty-five to forty million gallons will be needed, and the new system proposed will provide this amount of filtered water.

Capt. Symons proposes to use a modification of a system which has been in use in manufactories for some time. He has found that certain engineering difficulties can be overcome, and can see no reason why it should not be a success. The system requires the use of fourteen steel tanks 30 ft. in diameter and 17 ft. high. 8' 10" up from the bottom each tank is divided into two compartments by a stout diaphragm. The diaphragm is perforated by valves and by two large pipes which extend nearly from the bottom to the top of the tank. In the lower compartment is placed about 8 ft. of sand and powdered coke. The valves being shut in the pipes and diaphragm the water is run in on top of the sand and coke and between it and the diaphragm. After percolating through the filter it is run out, ready for use, by an outlet pipe at the bottom. This process is helped by the pressure of the incoming water. When the filters are to be washed, the inlet water is thrown by means of valves into the outlet pipes, the valves in the pipe perforating the diaphragm are opened, and the whole mass rushes with violent agitation into the upper compartment, which is open to the air. The heavy coke and sand are here allowed to settle, while the water which contains the filtrate is run off by an appropriate pipe. The filtering material is then got back into the lower compartment by opening the valves in the diaphragm, being at the same time a second time flushed with water. The river water is now led in by the inlet pipe as before. The first that comes through being somewhat muddy, is conveyed to the upper compartment to be used in the next washing. Each

tank is independent of the others and can be cleaned without cutting off a sufficient supply of water.

The very undesirable loss of "head" which the water sustains in filtering can be more than compensated for by the introduction of centrifugal pumps in the circuit. These pumps are designed to be run by the waste water from the washings with any necessary addition. Previous to leading the water to the filters it is proposed to intimately mix it with one-fifth its bulk of atmospheric air and a certain very small proportion of alum. With these last two additions it is hoped that both the inorganic, the albuminous, gelatinous and ammoniacal matters will be oxidized or precipitated so that they can be easily filtered out.

The experiments of Prof. Frankland, of England, and other chemists, have proved that after being subjected to the above processes, water comes out clear and sparkling, and freed from almost all of its organic and inorganic contents.

The distributing reservoir just west of Georgetown is divided into two parts by a wall. The upper lake contains about 110,000,000 gallons and the lower about 60,000,000 gallons of water. It is proposed to set up these filters between the two parts, to use the upper one as a subsidence reservoir, and the lower one, from which run the city supply pipes and the new tunnel, as a receiving reservoir for the clarified water. He thinks this plan perfectly feasible, economical and efficient.

DR. REYBURN asked where alum was in use?

CAPT. SYMONS replied he had seen it in Somerville, N. J., and it had a wonderful effect. Albany was about to put up similar arrangements.

DR. ANTISELL remarked that the removal of inorganic matters was the first and most important step in this case. He thought that it would be a long time before organic substances in the Potomac would give us any alarm. What we wanted chiefly was the removal of the mud which appears after every heavy rain. This had been accomplished in Europe by good filtering beds. This system he thought the cheapest and best. Aeration was being used in Philadelphia and other places, and was well enough, but the sediment was the principal inconvenience. The method of Hyatt which was proposed he was unfamiliar with.

CAPT. SYMONS replied that the primary object of this system was just what the doctor advised, and that it was much cheaper than the filter bed system, both in first cost and maintenance.

DR. REYBURN said that it had been conclusively shown that proper filtration removed bacteria as well as inorganic matter, and that even when organisms were in great numbers they could be nearly eliminated.

DR. ANTISELL said that in all certainty there were bacteria in the water, but he never had heard that they had done any harm. It was well, however, to have water as free as possible from them.

DR. KING said that he had recently been conversing with Dr. T. Smith, who had informed him that the water of some European city contained 20,000,000 bacteria to the litre, and ours only 3,000,000.

CAPT. SYMONS, in reply to a question as to the cost, said that he did not know, but it was certainly less than the filter bed system.

DR. TONER asked if it were not possible to use Powder Mill Creek as a subsidence reservoir; and if analyses of our water are being made from time to time?

CAPT. SYMONS replied that it was perfectly possible to use the valley of a stream for a reservoir, and that estimates had already been made in this case as suggested. He said that Dr. Theobald Smith and Dr. Billings had made analyses. He further remarked that the impurities in our water were of such a light nature that they took from three to four weeks to settle, which was too long a time for the good of the water in this climate.

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Inoculations for Rabies—Influence of Diabetes on Gestation—Fumigations with Tar and Turpentine in Croup.

The treatment of rabies by inoculation seems to have taken an unfavorable turn lately, for within the last three months there have been no less than six deaths reported from hydrophobia in persons who had returned home after having gone through the process of M. Pasteur's inoculations. On the 27th of April last a young girl of 11 years of age was bitten by a dog at Chassagne (Jura). Nine days after she was brought to M. Pasteur's laboratory and went regularly through the ten inoculations prescribed. She remained in Paris fifteen days altogether, when she was pronounced cured and sent back to her family. On the 13th of June, that is, forty-eight days after she had been bitten, or thirty-nine days after the first inoculation, symptoms of hydrophobia set in and she died on the 17th of June.

The *Journal de Médecine de Paris* reports that one of the Russian women who had been inoculated at M. Pasteur's laboratory after having been bitten by a wolf has just succumbed to rabies at her own home, whither she had returned "completely cured," according to the expression adopted by M. Pasteur. This death makes the fourteenth of the fifty-four persons bitten by wolves, which would give a mortality of about 26 per cent. On the 21st of July a man aged 35 died at Grenoble from hydrophobia. He had been bitten on the hand by a rabid cat on the 30th of April last, and had gone through the preventive treatment at Paris from the 4th to the 13th of May. This makes the fourth death from hydrophobia of the persons who were treated at M. Pasteur's laboratory, exclusive of the Russians bitten by mad wolves. A letter from St. Petersburg reports that on the 3d and 4th of May last seven persons (five children and two women) were bitten by a mad dog. They were sent on to Paris under the care of a doctor, to be treated after M. Pasteur's method. Of these seven patients, three have died since their return to Russia.

A rather comico-scientific conference was lately

held in Paris, the object of which was to criticise the so-called anti-rabic inoculations of M. Pasteur, the actual efficacy of which is questioned in certain quarters. The officers were recruited principally from the Paris Municipal Councillors, and were it not that some of them belong to the medical profession, the proceedings of the meeting would not have been noticed here. One of the speakers, M. Paul Bouillier, a veterinarian, member of the Paris Municipal Council, began by stating that there were no microbes in rabies, or if there was any discovery made in that direction it was not due to M. Pasteur, but to a physician at Toulouse whose modesty has prevented him from claiming the right of the discovery. Moreover, this worthy veterinarian stated that M. Pasteur's inoculations have no effect whatever in preventing hydrophobia; that the method in question serves only to produce meningitis and nervous affections, and that those supposed to have been cured were never affected by the rabic virus of the animal that bit them. He has even challenged M. Pasteur to put his method to a personal test: he and his adversary are to be bitten by an undoubtedly rabid dog. Then the Councillor is to be cauterized, and the Professor inoculated. The contest will be decided when one of them goes mad.

Another speaker made out that according to an official communication, the number of persons inoculated to this date at M. Pasteur's laboratory amounted to 1,630. Among these there have been only twelve deaths: five persons have succumbed to the bites of dogs, one to that of a cat, and six to the bites of wolves. Here M. Bouillier, interrupting, suggested that these patients died from one or other of the diseases above referred to, viz.: meningitis or a nervous affection.

Another critic recalls that M. Pasteur had made the positive announcement that his method would protect even if one or two years had elapsed after the bite. This time was subsequently reduced to thirty-five days, but afterwards he even limited it to fifteen, and now, since the more recent deaths, he will be obliged to reduce it still further to thirteen days.

In an interesting paper by Dr. Lecorché which he lately read before the Medical Society of Hospitals, on the *Influence of Diabetes on Gestation*, the author has shown that diabetes does not render women sterile. He had six diabetic patients who were delivered of children at full term, but they were all delicate. According to this physician, when diabetic women are sterile, it is due to uterine lesions resulting from diabetes. Diabetes has direct influence on the process of gestation, impairs foetal nutrition, and is favorable to faulty development, especially hydrocephalus. It often produces dysmenorrhœa and amenorrhœa, and an early menopause often results from an overlooked diabetes. If the sugar disappear, the menses may return.

A short time ago Dr. Delthil vaunted the use of *Fumigations of Tar and of the Essence of Turpentine in the Treatment of Croup*. At a meeting of the Medical Society of Hospitals, Dr. Cadet de Gassicourt said that from his experience these vapors had

no solvent action on false membranes placed in the open air. He had tried the method in twelve cases at the hospital, all of which nevertheless necessitated tracheotomy. Four of these were cured and eight died. The fumigations are not well borne, and after the operation they cannot be continued, as they rapidly obstruct the tracheotomy tubes, and at the autopsy coal-like parcels were found in the bronchi, which is one of the dangers of this treatment, which should be rejected. In fact, Dr. Delthil himself has given it up, and contents himself with simple inhalations, at a distance, of the vapors of the essence of turpentine.

A. B.

NECROLOGY.

DR. CHARLES H. LIEBERMANN,

of Washington, one of the oldest and most accomplished physicians of that city, died at his residence, 722 Twelfth street, N. W., on March 27, 1886, in his 74th year. He was born in Riga, the capital of the Province of Livonia, in Russia, on September 15, 1812. His father was a military surgeon, and died while the subject of this sketch was a child. His mother belonged to the family of the Radetzkeys, which has furnished many famous personages in German and Polish history. The doctor's uncle became his guardian, and faithfully carried out the injunctions of his father to give the child a good education. He passed through the usual course of the gymnasium, after which he entered the University of Dorpat, from which he graduated in letters and the natural sciences in 1836. From Dorpat he went to Wilna, where he pursued for a time the regular medical studies, but after some time he returned to Dorpat, and from there he went to the University of Berlin, from which he received his medical degree in 1838. In Vienna he became a private pupil of Prof. Diefenbach, and served for some time as his assistant, and became entirely familiar with that eminent surgeon's improvements and methods of practice in surgery. This was at a period when the profession of Europe was making rapid advances in the study and treatment of a class of cases which fell rather under the denomination of deformities, than that of diseases, and which had been everywhere much neglected. At the head of these might be placed strabismus and club-foot. Dr. Liebermann enjoyed the advantages of the lectures and clinics of the famous von Graafe, in his treatment of affections of the eye. This surgeon was then among the most noted practitioners of Europe in this specialty. After receiving his degree Dr. Liebermann visited the chief capitals of Europe to familiarize himself with the practice of medicine and surgery in their best hospitals.

Dr. Liebermann came to the United States early in 1840. He landed at Boston, but had conceived a desire to settle in Washington. This preference was probably developed because of the political views he entertained and the disagreeable experiences he had already suffered from the despotic regulations exercised over the actions of the private

citizen in his native land. He began the practice of his profession in Washington shortly after his arrival, opening an office on the north side of Pennsylvania Ave., between 9th and 10th streets. The following is a copy of his first newspaper advertisement, which I have seen. It is taken from the *National Intelligencer* of March 17, 1841: "Dr. Charles H. Liebermann has removed his office to the basement of his residence, northwest corner of 11th and F streets. Dr. L. is ready at all times to advise or practice either medicine, surgery or midwifery, for the poor gratis, not excepting capital operations. March 17, 1841."

After a residence at this F street location for about two years he returned to Pennsylvania Ave. and took a house on the south side, between 9th and 10th streets (see Washington City Directory for 1843). The following notice relative to Dr. Liebermann appeared in the *National Intelligencer* of May 25, 1841, and as it gives some information not otherwise met with as to the Doctor's professional education, and the esteem in which his skill and abilities were held by his teachers and fellow-students, it is copied in part: "*Strabismus, Cataract, and Clubfoot.*—In the last number of the *Medico-Chirurgical Central-Zeitung*, of Berlin, we notice the following paragraph, published by the professors of Berlin: Dr. Charles H. Liebermann, formerly a student at our University, who so eminently distinguished himself here by his attainments as a physician, surgeon, and oculist, has emigrated to the United States of America. While we believed him yet journeying in the Western hemisphere for the purpose of selecting a suitable locality as the theatre of his professional labors, we were agreeably surprised and now sincerely rejoice to see it announced in some of the public papers of that country that Dr. Liebermann had already and with signal success performed there our newly discovered operation for the cure of strabismus, or squinting, as well as several operations for the cataract and clubfoot."

Professor Dieffenbach, the originator of the operation for the cure of strabismus, adds to the above the following: "Dr. Liebermann, who has been one of my distinguished pupils, and for some time after closing his academical course, my associate in the practice of medicine and surgery, was, after myself, the third physician in Europe and the first one in the United States who, as early as October last (1840), performed the operation for strabismus with complete success."

The medical profession of the United States, as well as the politicians of the country, saw with some regret the rapid emigration and the prominent positions given in the professions and public places requiring scientific acquirements, to foreigners. Dr. Liebermann had to contend with this feeling, but he was so well equipped in professional attainments, and was so discreet and honorable in his intercourse with medical men, that he soon gained not only the high regard of his brother practitioners, but of the citizens in general, which he retained to the close of his life. He identified himself, as soon as practicable, with the profession of the city by joining the

Medical Society of the District of Columbia, which he did in 1844. He held in it, at different times, many of its offices, and was its President from 1865 to 1868. He is registered as joining the Medical Association of the District of Columbia in 1843. He was also a member of the Columbia Institute, which had in it a section devoted to medical science. This was, before the days of the Smithsonian Institute, an active scientific organization. He was one of the founders of the Medical Department of the University of Georgetown, and filled the chair of Professor of Surgery from 1849 to 1853. He again filled the same chair from 1857 to 1861, when he resigned, and was elected Emeritus Professor of Surgery. He was also a member of the first Pathological Society of Washington, organized in 1841; also a member of the American Medical Association in 1858. He was well calculated by natural abilities, as well as by his thorough literary and professional training, to make himself interesting in the discussion of diseases, their cause and treatment. His tastes, however, led him to surgery, in which he excelled. He had much mechanical ingenuity, which enabled him to succeed in the treatment of cataract, joints and deformities. He was for over twenty years the leading oculist in Washington. He was for years physician to the Sisters of the Visitation Convent, and the consulting physician to Georgetown College and the Convent in Georgetown. He was also a member of the staff and consulting surgeon to the Providence Hospital for a number of years.

He was systematic and thorough in whatever he engaged in, and was thus enabled for years to attend with punctuality and efficiency to a large and lucrative practice. He took an active part in the founding of the Children's Hospital, and for some years served on its Board of Managers. In the efforts made by the Medical Society of the District of Columbia to build a hall for its meetings and the storage of a library, he was one of the leading advocates and financial friends, and although the project failed, the profession retained for him and his exertions in its behalf a kindly recollection.

He was married in 1841 to a Miss Betzold, of Alexandria, by whom he had two children, a son and daughter. Charles only survives. In 1872 he retired from the practice of medicine, removing his sign from the door. He has occasionally since met physicians in consultation in cases of old patients, when strongly urged to do so, but has never assumed charge of a case since. His mental powers to the last seemed as active and strong as in the middle period of life. While he was of delicate constitution, his life was so regular and prudent that he was enabled to perform a great deal of labor. He was a man of marked traits of character; his tenacious memory for details was rarely equaled. He had at the same time an orderly and logical method of reasoning, and was pertinacious in getting direct answers to his questions, put to patients or persons on matters of business. In every-day life he was methodical and exact. He lived well, but not extravagantly, extertained his friends occasionally at his table, and was a capital host.

The Medical Society of the District of Columbia met in special meeting on March 29, and passed resolutions expressive of the esteem in which he was held, and of sympathy for his family, and resolved to attend his funeral in a body.

J. M. T.

DR. GEORGE SUTTON.

At a regular meeting of the Dearborn County (Indiana) Medical Society, held in the Court-House in the City of Lawrenceburg on the 29th of June, 1886, the following preamble and resolutions were unanimously adopted, to-wit:

WHEREAS, It has pleased the Great Creator and Ruler of the Universe to remove from our midst our friend, associate and professional brother, Dr. George Sutton, and

WHEREAS, In view of the very great loss this Society has sustained by this event, and in view of the greater loss to the profession at large, and the great loss sustained by the various scientific bodies of which he was an honored member, and still the greater loss to his family and relatives. Therefore be it

Resolved, That it is but a just tribute to his memory to say, that in regretting his removal from our midst, we mourn for one who was in every way worthy of our highest regard as a friend and professional associate, and of the greatest esteem, as a neighbor and a citizen.

Resolved, That we sincerely sympathize with the daughter and son, on this dispensation with which it has pleased Divine Providence to afflict them, and we commend them to Him who orders all things for the best, as He is too wise to err, and too good to do wrong.

Resolved, That a copy of this preamble and these resolutions be spread on the records of this Society, and that a copy be sent to the afflicted family; also a copy be sent to the *Cincinnati Lancet and Clinic*, and to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

BOOK REVIEWS.

MEDICAL AND SURGICAL DIRECTORY OF THE UNITED STATES. 1455 pp. Detroit: R. L. Polk & Co. 1886.

In this Directory the publishers have supplied a much needed work. It not only gives a list of physicians and surgeons arranged by States, but an immense amount of other information of interest to the profession and those having business relations therewith. It contains the names of nearly 80,000 persons practicing medicine within the United States, conveniently arranged, accompanied by all the information attainable regarding place and time of graduation, etc. A good descriptive article is given with each State list

embodying such matters as location, boundaries, extent in miles and acres, latitude and longitude, statistics regarding climate, temperature, population, rate of mortality, number of deaths from consumption, all medical and charitable institutions, medical societies, and the full text of all State laws relating to the profession. There is also a complete list of all medical colleges, either existing or extinct in the United States and Canada, of officers of the medical departments of the U. S. Army, Navy, Marine Hospital Service and pension department, and a complete directory of the medical journals of the United States.

The publishers have successfully accomplished a work of great magnitude in collecting, correcting and arranging in such an excellent manner the army of doctors belonging to the various pathies in the United States. The arrangement and display of the advertising department is unique, and the general typographical appearance excellent. It is intended to publish the work at regular intervals.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

MILK-POISONING AT LONG BRANCH.—An outbreak of illness from bad milk has recently occurred at Long Branch in the Ocean Wave Hotel. A large number of the guests and attaches were made ill, suffering from vomiting and purging. The proprietor was able to trace the trouble to milk, which had become stale on the dealers hands, and to which he had added chemicals to preserve or freshen it.

THE BRITISH MEDICAL ASSOCIATION AND THE INTERNATIONAL CONGRESS.—A cablegram to the *New York Medical Journal* from Brighton, giving an account of the meeting of the British Medical Association, says: "The American delegation present, including Dr. Davis and others, made a statement before a crowded general meeting in regard to the affairs of the International Medical Congress. The delegates were received with enthusiasm, and their renewed invitation to the members of the Association to visit Washington in 1887 was cordially accepted."

ADULTERATED MILK IN CHICAGO.—The Health Department of the City has found that dealers are skimming and watering the milk put upon the market. Those against whom there is evidence will be arrested and dealt with.

NEBRASKA STATE MEDICAL SOCIETY.—At the late annual meeting of this Society the following officers for the ensuing year were elected:

President, Richard C. Moore, M.D., of Omaha; 1st Vice-President, Milton Lane, M.D., of Lincoln; 2d Vice-President, N. F. Donaldson, M.D., of North Platte; Cor. Sec., H. B. Lowrey, M.D., of Lincoln; Rec. Sec., A. S. von Mansfelde, M.D., of Ashland.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM AUGUST 7, 1886, TO AUGUST 13, 1886.

RETIRED.

Brigadier-General Robert Murray, Surgeon-General U. S. A. August 6, 1886.

Major Wm. D. Wolverton, Surgeon, granted one month's leave of absence, to commence on or about Aug. 15, 1886. (S. O. 104, Div. of the Atlantic, Aug. 7, 1886.)

Major Edwin Bentley, Surgeon, ordered from Dept. Texas to Dept. East.

Capt. D. M. Appel, Asst. Surgeon, ordered from Dept. East to Dept. Texas. (S. O. 179, A. G. O., Aug. 4, 1886.)

Capt. Leonard Y. Loring, Asst. Surgeon, granted leave of absence for one month, on surgeon's certificate of disability, with permission to apply for an extension of two months. (S. O. 59, Div. Pacific, Aug. 2, 1886.)

Capt. Geo. W. Adair, Asst. Surgeon, ordered for duty as Post Surgeon, Ft. Brady, Mich.

First Lieut. Chas. M. Gandy, Asst. Surgeon, granted leave of absence for one month, with permission to apply for one month's extension. (S. O. 103, Div. Atlantic, Aug. 6, 1886.)

Capt. James C. Merrill, Asst. Surgeon, assigned to duty as Post Surgeon at Ft. Klamath, Oregon. (S. O. 130, Dept. Col., July 30, 1886.)

Capt. Robert B. Benham, Asst. Surgeon, ordered from temporary duty at Ft. Omaha, Neb., and ordered to Ft. Bridger, Wyo. (S. O. 97, Dept. Platte, Aug. 5, 1886.)

APPOINTMENTS.

To be Asst. Surgeon, with the rank of First Lieutenant:

Henry S. T. Harris, Jan. 5, 1886.

Leonard Wood, Jan. 5, 1886.

William B. Banister, Jan. 26, 1886.

Charles F. Mason, May 5, 1886.

PROMOTIONS.

To be Surgeon, with the rank of Major:

Capt. John H. Bartholf, Asst. Surgeon, Jan. 4, 1886.

Capt. James P. Kimball, Asst. Surgeon, Jan. 24, 1886. (A. G. O., Aug. 2, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING AUGUST 14, 1886.

Walton, Thomas C., Surgeon, to remain on present duty until Sept. 1, 1887.

White, C. H. Surgeon, to remain on present duty until August 21, 1887.

Rush, C. W., P. A. Surgeon, authorized to delay ten days, under orders to Sitka, Alaska.

Lumsden, G. P., P. A. Surgeon, ordered to hospital, Mare Island, Cal.

Baldwin, L. B., P. A. Surgeon, ordered to U. S. S. "Ranger."

Neilson, J. L., Surgeon, detached from the U. S. S. "Ranger," to proceed home and wait orders.

ADDRESS.

A GENERAL PRACTITIONER'S VIEW OF THE CAUSES AND PREVENTION OF INSANITY.

The Address in Mental Disorders, Delivered at the Thirty-Seventh Annual Meeting of the Medical Society of the State of Pennsylvania, June 3, 1886.

BY JOHN T. CARPENTER, A.M., M.D.,
OF POTTSVILLE, PENNSYLVANIA.

The appointment to deliver the address in mental disorders, which I had the honor to receive at our last session, came to me unsought and undesired. I am as mindful as any of my colleagues can possibly be, how ably this appointment has been filled during previous years—filled by experts in mental disorders, by members of the Association of Medical Superintendents of Insane Asylums, and by recognized authorities in this great Specialty of Medicine. To follow such predecessors on this occasion, in some way that may justify one who is only a general practitioner of medicine, in speaking of what most intimately concerns a select few of his colleagues—and to address this learned body upon a specialty which each of us, for long years past, has been accustomed to consider as under the guardianship of its own appointed medical “keepers”—seems to me difficult of accomplishment, and the very undertaking liable to be considered almost an impertinence. Under these circumstances I must ask your indulgence, reminding you that this duty was imposed upon me by our President, and that I am endeavoring to make a contribution to the common fund of our medical experience, if not in my own chosen direction, at least in the way assigned me. The willing obedience to lawful authority which has always distinguished the members of this Society, must be my excuse and reason for this address.

I propose to make some remarks upon the “Causes and Prevention of Insanity,” as seen from the outside point of view of the general practitioner. Most medical men are wont to give thought to these topics—to discuss them with themselves and with their colleagues—on account of the apparent steady increase of mental maladies for years past. To most observing men in the profession the increase of insanity seems out of due proportion to the increase of general disease. An ever greater ratio of the population of our Commonwealth is annually brought under treat-

ment for mental alienation. The number of hospitals has been increased—private institutions have been multiplied—and the number of the insane who are treated in county almshouses does not perceptibly diminish. The causes of the increase of mental disorders require to be carefully sought out, and if possible, remedied. To the average general practitioner the study of prevention seems to be our chief need. To search out the causes of the mischief and eradicate them, seems also to be a duty which we can share with the alienist physicians. In this quarter seems to appear, if not the only, at least the chief hope, in our struggle against the spread of insanity.

The cure of an established mental alienation, by even the best hospital treatment, does not occur in any very satisfactory ratio to the whole number of cases treated. It is feared that the frequently claimed 40 per cent. of cures does not usually result from treatment. I am well satisfied that, of all the cases sent by me (or known by me to have been sent) to hospitals for the insane, in the last thirty years, an average of 20 per cent. would more nearly represent the number who have been restored to mental health and usefulness. Let me repeat the statement in another form, and say that in my own experience, 80 per cent. of the insane whom I have known treated in hospitals, have never recovered. This is a sad commentary on the inefficiency of our best directed efforts. It is a disheartening return of the results of the vast expenditure lavished on our public institutions, where no sanitary or hygienic measures are omitted, and where no medical or surgical skill is spared the afflicted patients.

And if this be true of our admirable public asylums, how much darker a picture could be drawn (and drawn from the life) of their condition and prospects who linger out a forlorn and distracted existence in county almshouses, or in private dwellings—restrained of their liberty, unoccupied, uncheered by social amusements, unheeded too often—a heavy burden, and an illy tolerated curse, upon the household or the community. What a fearful percentage of uncured would we reckon from the class of these unfortunates, if their statistics could be gathered together and read before us to day!

But there is a still more unfortunate class of the insane. Every now and again the sensibilities of our common humanity are shocked, and swift indignation thrills every fibre, at a revelation of cruel bondage and solitary suffering, in squalor, filth and mental misery, of some poor lunatic; hidden away (chained

down perhaps) by a brutal and cowardly keeper, coarsely fed, ill-treated, and subjected to whatever injuries are most calculated to brutalize and degrade him. Dragged to the light of public knowledge, such wrongs are swiftly ended; but how many similar cases may we not suppose to have never seen the light—how many more such unfortunates, who lived some such existence of misery, and died unrecorded in insane statistics—never to be known till “the books are opened” and the recording angel unfolds the fearful history of their sufferings. In such cases as these, be they many or few, there is no cure. For them there is no percentage of recovery. “Death comes to set them free.”

Into such a practical classification as that just given, the insane of our great Commonwealth may be placed, and the medical profession has its special duties with reference to each. The class last-named should not be allowed to exist among us, to disgrace our humanity and civilization. To right the distresses of these sufferers, no exertion should ever be spared. Whenever such cases are discovered, in our daily visitations from house to house, at whatever cost of personal trouble, or even of obloquy, the aid of the law should be invoked, and the power of public opinion be aroused to deliver from worse than death these helpless victims of “man’s inhumanity to man.” The only measure of our duty is the extent of our ability. When we have done our utmost, at every hazard, then only may we rest content.

The insane of our public institutions are the fortunate recipients of the full measure of the most enlightened methods of treatment and means of cure. We are released from responsibility, as far as they are concerned, when we have secured their admission to the asylum or hospital. Nevertheless we are not relieved from the duty of personal sympathy with their condition. Such frequent inspection of public institutions, and conferences with their medical officers, as will manifest our interest, and refresh our general knowledge of modern methods in the treatment of insanity, are necessary to keep us *en rapport* with that devoted body of medical men, who illustrate the annals of the profession by spending their time, their abilities and their lives in mitigating the direst woes that can befall humanity.

There remain the pauper insane of county almshouses. The late laws enacted for their protection, have need to be rigidly enforced. The inspections of the local boards, appointed to assist the State Board of Charities, are most valuable in this direction. But they should be reinforced, everywhere, by an affiliated committee of the County Medical Society. The insane poor need medical guardianship, and it can not be better afforded than by our County Medical Societies. By regular and by unexpected visitations and reports, and by appeals to the proper authorities, founded on such medical inspections, it will become possible to obtain, under the law, despite the parsimony of Directors of the Poor in such matters all necessary accommodations and means of cure for the pauper insane. It should not be permitted that these unfortunate sufferers be left in careless, unfeeling and unskilled hands. Each county medical

society should endorse or condemn as a sacred duty, the men and the methods, by which cure is or is not, successfully conducted. Every county almshouse should be forced to take as good care of its insane inmates as is done in our public hospitals for the insane. This should be the aim. No less should be asked or accepted. And it is for the medical profession to accomplish this great work. It is ours by virtue of our calling, by our humanity, by our knowledge and by our proper leadership in every movement which looks toward the improvement of the physical or mental condition of men. But we must proceed with our main consideration. If we find cure so infrequent, remedies so uncertain, and the increase of mental maladies so progressive, what can be done to prevent their development in the community? Has not insanity evident causes which may be studied to such purpose that, being forewarned, we may also be forearmed against them? It seems to be evident that the study of statistics affords but little aid to this inquiry. They are too imperfect to be reliable, and need to be supplemented by accurate study of each separate case submitted, to become really trustworthy evidence.

The only scientific method would seem to be to regard insanity as a part of the diseases of the nervous system, and to study its causes as related to (and inseparably connected with) those general, constitutional conditions which medical practitioners have learned to recognize as causes of general nervous derangements. The physician who has been accustomed to treat hysteria, epilepsy, hypochondriasis, delirium, spinal and cerebral sclerosis, paralysis agitaus, chorea, *et id genus omne*, and who has carefully studied the exciting and the predisposing causes in these other nervous disorders, should be qualified to speak with some authority of the causes of insanity. Related anatomically as they are, by their seat in the nervous tissues, they are also related by virtue of common constitutional causation. For insanity is not a simple or single condition of disease, but under that term is comprised as large a number of diseased states of the brain as is to be found in the general nervous system itself, among diseases which I have just enumerated. It is only because of the predominant symptom of mental defect or disorder, that such varied diseased conditions of the brain are comprehended under the general term, insanity.

What, then, is the most prominent fact which impresses itself on the observation of medical men, as to the causation of nervous diseases? I answer the existence of a family constitution tending to nervous instability, materially influencing the development of the nervous system, and making itself felt by a tendency to degenerative changes in the nervous tissues. Such neurotic diatheses renders its subjects liable to break down under stress of circumstances which would not affect persons of a different constitution. How many of us have been acquainted with families, whose members have illustrated the close relation of nervous diseases, by exhibiting examples of a great many of them within their family circle? Let me cite, by way of example, a father affected with locomotor ataxy, one of his children dying of tubercu-

lar meningitis, another stricken with epilepsy, a third having hysterical hip-joint, a fourth experiencing attacks of aphasia, a fifth becoming a confirmed dipsomaniac, and the sixth a victim of chronic mental disorders. This family was, for a long period, under my personal medical care, and I studied their cases with the greatest interest. Surely there is no difficulty here, in recognizing the correlation of the various nervous diseases with insanity. For such widespread family disaster I found no other common cause than an inherited neurotic diathesis—and there certainly was none. Take another set of cases, also within my own knowledge, which will illustrate this point still further. A mother died of dementia, her son is the victim of chronic alcoholic excess, one daughter died of convulsions, a grandchild has infantile paralysis, a second succumbed to meningitis.

But it seems unnecessary to multiply these family histories. They are well recognized by numbers of general practitioners as proofs of the inherited neurotic diathesis being the chief cause of nervous diseases.

Let us look at another constitutional state as a fruitful cause of insanity, viz. syphilis. Many cases of the so-called general paralysis of the insane are instances (as proved *post-mortem*) of syphilitic disease of the brain. Under the same causation of syphilis may be classed much of the traumatic insanity met with. The chronic slumber of constitutional specific disease is wakened into activity by a blow on the head—the traumatism only being the *exciting* cause. In such instances, the constant headache—the outbreaks of violent rage—the strabismus—the locomotor disturbances—all point to intra-cerebral pressure. Mental disorder soon becomes manifest. Epileptiform convulsions mark the advanced stage. When death allows the cerebral lesions to be investigated, there is often found the syphilitic gumma and degenerative arterial changes, to explain why insanity followed perhaps an apparently trivial injury. In this connection I may refer to Dr. H. C. Wood's paper on "Traumatism as a Cause of Cerebral Syphilis," as a most valuable contribution to our knowledge of the subject.

To make practical use of these truths in the prevention of insanity, if we can treat families with the neurotic diathesis in such a manner as to improve the general health, to strengthen the nervous system, and to remove sources of peripheral irritation, there is reason to hope that many causes of possible insanity may be prevented from becoming effective in such families, under medical care. And, first in order, we must begin with the children. Homes must be regulated under every hygienic precaution. Attention must be paid to the food—personal habits of cleanliness, open-air exercise, and early hours of sleep must be insisted on—and suitable amusements must be provoked for their recreation. Over-work, whether of body or mind, must be avoided. The over-wearied body is an easily sickened body. It responds too readily to depressing influences. It suffers too keenly from external irritations. The over-wearied mind is even a more serious disaster in subjects of the neurotic diathesis. The strain of

modern methods of education often needs to be relaxed. The public school system has become too much a children's tyranny. The uniformity of attainment exacted, from weak and strong alike, the prolonged hours of sedentary mental labor, the competitive system of marking and examination, the worry of a feeble mind in trying to study at a rate beyond its capacity, the insufficient time allowed during school hours for recreation and physical exercise, and the mental distress of sensitive, neurotic children under punishment or threats of punishment—all combine to make the system of public school drill and discipline, too often a remorseless engine of mental torture. For the pace must be kept up, the slow must travel with the fast, the weak must wrestle as do the strong, whether it develop or whether it exhaust the fibre.

Above all, therefore, it behooves the family physician in neurotic families to take oversight and authority in educational matters, and to protect the children from the consequences of undue mental work and worry. Then we may expect nervous distress and nervous diseases to diminish among them, and insanity to be often disappointed of a ready prey.

In the case of older members of neurotic families, over-work means also over-worry. Ambition, anxiety, disappointment wear out the fine temper of the mind. A state of unstable equilibrium results, and too often degeneration of brain structure is the result of the unequal struggle, when too long protracted. Given a naturally feeble mental machinery, and the determining causes of its loss of working power are over-work, with consequent diminished periods of necessary rest and recreation. Let every medical man give the utmost attention to the prevention of these exciting causes of brain disease, for they are first in importance. Next to these follow the abuse of stimulants and narcotics, which has much to do among the excitable and irritable American people with the aggravation or even calling into activity the tendencies to insanity. The first abuse of these agents is in their too early use. Boys too soon acquire the habit of indulgence in tobacco. Young men too early habituate themselves to indulgence in alcoholic stimulation which unhinges the mental machinery by direct injury to the brain tissues. Undue excitation brings rapid exhaustion. Local brain congestions, transient though they be, at last induce structural degenerations, and in chronic alcoholism (independently of gouty insanity, which I have had occasion to see) dementia from softening will often be found to occur. Lastly, among the exciting causes which act upon the neurotic constitution to induce insanity, are those which are purely mental as distinguished from physical causes.

In the keen strife for wealth, for political success, and even for livelihood, are to be found many of the events which determine the wreck of the mental forces. Among them we may enumerate the tremendous strain of speculative operations in the stock markets, with their hourly fluctuations in values, unforeseen and unmanageable, which make all the difference between ruin and opulence, between wealth to-day and beggary to-morrow. In the political arena

we can to-day trace the results of a protracted national contest, with its accomplished overthrow of the dominant party, the consequent loss to so many office-holders of place and means of support, while on the other hand, there is eager pursuit of office by numbers of needy men, who only meet bitter disappointment or anxious delay. And in the pursuit of the ordinary means of livelihood we have seen the laboring classes engaged in fierce and protracted contests with their employers—labor and capital at war—under circumstances which inflame the fiercest passions to the utmost tension, and inflict long periods of sorest distress upon the community. All the wear and tear of the cruel mental suffering which these events bring with them, intensified by the mobile and irritable national character, are constantly trying to the utmost the mental endurance of our people. Hundreds go down under the stress of such circumstances, after having experienced the fluctuations of hope, doubt, anguish and despair for weary months—buffeting the waves which finally engulf them, when there is no longer strength left to struggle.

It seems to be timely, in view of all these considerations, for medical men to sound the note of alarm, and to call the attention of those under their influence to the dangers to mental stability involved in American modes of life. Men must be advised to moderate their pursuit of wealth, to put away inordinate ambition, to shun the fierce conflicts of partisan politics, and to avoid being involved in labor disturbances that tend to civil war. We must insist that violent excitements and great anxieties can not be successfully endured, and that the choice of a life which involves constant subjection to those evils is a folly, and may be a crime.

It is well, at this era of our national life, for the doctor of medicine to be what his title implies, a teacher; and to combine, as was done in distant ages, the sacred offices of physician and of prophet. It is for our profession to utter prophetic warnings against the habits, the pursuits and the tendencies which unsettle men's minds, and bring misery upon all their future. It is our duty to point out the dangers of excited, overstrained and ill regulated mental habits. And if there be any exhortation more necessary to give than another, it is that men should lead quiet, sober, healthful and peaceable lives, as the great preventive against the increase of insanity. We must advise against indulging in exaggerated modes of thought and expression, against habitual yielding to the excitements of passing events—in fine, against the *hysterical temperament* which seems to be taking fast hold of the American people, and disabling them from seeing things as they really are—making them enjoy feeding on horrors, sensations and exaggerations of every sort—disdaining human nature's daily food, as not appetizing enough for their diseased mental palates. The public press unfortunately, is the ready provider of what they crave. Unsavory news is gathered from every quarter—crimes are recited in disgusting detail; disasters are tricked out with all the ghastly coloring of the skilled chronicler—unclean gossip is not wanting, often unfit to be spoken, much less printed—graphic descrip-

tions of brutal prize fights find a prominent place—political slanders, lies and personal defamation of character are not carefully excluded. All this printed daily, with a full measure of the grotesque and coarse so-called wit and humor, goes to make up the mental food of the average American, not food for making up clean thinkers and honest workers, but tainted as carrion flesh with foulness and decay a fermenting mass, in great part, fitted to keep up the seething process when introduced, and to leaven with its unwholesomeness, a vast number of receptive minds.

Against such brain food every healthy mind revolts and habitually rejects it. But the damage done to the unstable, the weak and the uncultivated can not be estimated. To them the newspaper is a revelation of life. They study and gloat over its worst details. The dramatically presented crimes have a horrible fascination, which may become potent in drawing by imitation and suggestion, many an unstable mind into their commission. The uncultivated and undisciplined drink in the subtle poison of sensationalism as if it were wholesome food. They "read, mark, learn and inwardly digest" it. The unreal, the false and the exaggerated are the staple of their daily thinking. Their standard of morals is lowered by continual mental contact with what is debased and criminal. Habits of truthfulness, thoughtfulness and earnestness are impaired. Emotional excesses are encouraged and self-control becomes fatally weakened. In fine, the American criminal, and the American "crank" are mental recipients from the daily press of much that is best fitted to aggravate and increase their inborn tendencies to evil. And the American people is daily imbibing what is surely calculated to develop and establish what I have called the "hysterical temperament" among them. Who will reform the sensationalism of the daily press? That man will deserve the everlasting gratitude of his countrymen.

Gentlemen, in this necessarily limited Address it would be impossible to do more than touch upon a limited number of the causes which may excite mental disorders in constitutions already prepared for their development. I have accomplished the purpose in view in writing this paper, if I have succeeded in calling the attention of my fellow practitioners of medicine to their opportunities, in those families committed to their charge, of averting mental disasters and mental ruin, by the simple method of attention to their education, to their habits and their surroundings.

GALVANO-CAUTERY IN DISEASES OF THE PROSTATE, BLADDER AND URETHRA.¹

BY ROBERT NEWMAN, M.D.,

OF NEW YORK.

Hypertrophy of the prostate gland is a disease from which most old men suffer. The gradual ad-

¹ Read in the Surgical Section, at the Thirty-Seventh Annual Meeting of the American Medical Association.

vance of the malady and its unavoidable complications, such as spasms of the bladder, retention by mechanical obstruction, cystitis, dilatation of the ureters, pyonephrosis and uræmia, make life a burden. A large majority of these sufferers succumb prematurely.

No rational treatment has thus far been adopted for the cure of this disease. Volumes have been written on the subject. Various methods have been suggested for the amelioration of the trouble and allaying of actual pain. A few cases have been reported as cured, either by injections, destruction, incision, enucleation, prostatotomy, etc., but no successful method of cure has been determined. Radical cures by surgery have been very few, most patients having died shortly after the operation. The great importance of establishing a method for the *radical* cure of the enlarged prostate no one can gainsay.

For the last five years I have endeavored to apply galvano-cautery directly to the hypertrophied prostate, but was unable to, from lack of a suitable instrument. Mechanics when consulted shook their heads, failed to construct the desired instrument or carry out my plans, and some declared it impossible to make my ideal instrument.

True, many difficulties had to be overcome. A smooth sound was needed of small size, easy of introduction to the spot to be cauterized. Both insulated poles had to be placed in the interior of this instrument, and the mechanism so arranged that the platinum could be heated to the desired degree instantaneously, with certainty and beyond possibility of failure. The cautery, its beginning, duration and ending, as well as the quantity used, must be under the absolute control of the operator. The platinum burner must not, in its entire length, touch anything, the heat must be concentrated, and not approach the surrounding parts of the instrument; the connections must be perfect and act promptly. The instrument must be light, small, handy, have the correct curve, and so arranged that the operator can manage the entire procedure without an assistant. The entire mechanism must be placed within the limited space of a No. 18 French scale sized tube. Next we must have a battery, so constructed as to give a certain quantity of electricity of a fixed potential, suited to the work to be done and the instrument; too high a potential will melt the platinum wires or cut the tissues like a razor; on the other hand, too low a potential will fail to heat the wire or not be effective. Therefore it is imperative to measure the electricity necessary for our work and instrument; for the same quantity of electricity under the same circumstances will always do the same work.

To fulfil these requirements in the construction of the instrument, was a difficulty which was overcome only by six months' constant hard work, trials, vexations, experiments, drawings and models, by myself and Dr. L. Drescher, to whose skill and labor I am largely indebted for the perfection of my idea. I am much pleased to exhibit and demonstrate here the result—the *galvano-cautery sound*.

The instrument is in the shape of a catheter, of smooth, polished metal, with a short curve. At the

end of its convexity is a fenestrum, in which is placed a platinum wire to be heated. This wire may be shaped differently, either straight, curved or serpentine, in order to get more or less surface cautery. The other end of the instrument is straight and forms the handle; from this end emerge two wires, the heat conductors, each of which is connected by binding screws to electrode wires, which respectively go to the positive and negative pole of the battery. The current-breaker is attached to one pole at the handle.

Any good galvano-cautery battery may be used with the instrument, but it is necessary, as before stated, to so regulate the battery that it yields the exact electrical potential to be used for the operation. I use a Dawson battery, which works to my entire satisfaction. Experiments are necessary to establish the standard. The heat must be of a high red color, just short of white heat, the instant the current-breaker is touched; this heat must be kept while the wire is in contact with the mucous lining. Less electricity is required to heat a free wire in dry air than to heat a wire held against a moist surface. The strength of the fluid is adjusted according to these requirements; the elements are immersed in the fluid to a certain depth, the electrode wires are regulated with regard to their size, length, etc.

Having determined these requirements for the operation, there will be no further trouble. It is a certainty that, in the near future, every scientific instrument-maker will construct his apparatus with the graduated measure needed, attached and regulated, so that the operator can use any measure desired. We can also use the storage-battery, consisting of a series of cells, which answers our purpose as well as for electrical illumination. This battery, once adjusted with reference to the quantity needed, works with equal power and steadiness till the stored electricity is exhausted. The last of its electricity has the same effect as the first. This instrument, though portable, is rather heavy. We may use the dynamo machine, which can be operated by hand, foot, hydraulic pressure or steam according to construction and desire. Such machine I have seen here in St. Louis at the store of Mr. A. S. Aloe (cor. 4th and Olive streets).

I repeat, no matter what kind of a machine is used, a fixed measure of electricity is necessary. You will see its action in some of the experiments; beginning with one flash of light, to be followed by several quick flashes. You have observed that the flash is simultaneous with the connection, which is important and absolutely necessary. If the wire is heated slowly, becoming warm and gradually hotter, till the desired heat is obtained, it shows that the instrument is faulty in its construction, consequently must be imperfect in its action. In experimenting with the instrument on mucous linings, we find that a galvano-caustic application of the same power acts differently according to the length of time of contact with the tissues. Thus the effects can be regulated from a light blush to the total destruction, or even amputation of the tissues.

It is a mistaken idea of many, that the galvano-cautery necessarily burns, destroys, and is followed

by cicatricial tissue. Nevertheless, this is a favorite objection of some ignorant persons and enemies of electricity. If the operator bungles, or wishes to destroy, he can, but the expert will not. It is well known that eminent neurologists apply galvano-caustic directly to the faces of young ladies, without ever causing marks. All depends on the manner of application. Even deeper applications on mucous linings may cauterize without destroying. Voltolini, Carl Michel, Shurly and Yemans, of Detroit, and many others, have applied the cautery to the nasal and pharyngeal cavities with great success. Therefore it is evident that different methods can be instituted with the instrument, and applied for various purposes to different parts.

We will now consider the application to the "enlarged prostate." Patients suffer more or less from this disease; they may be perambulant or in bed, or divide their time between bed and room; the hypertrophy may be small or extend to the size of an egg, or even an orange. Complications and pain may add beyond endurance to the sufferings. According to the state and circumstances the treatment must be selected, and the method applied. As some cases are beyond cure, the prognosis must be given cautiously, and according to the state of the patient.

The treatment which I prefer, and am now practicing, and alone recommend, and which has done good service, is the *slow (regular) method*. This means, give the enlarged gland a short application, from a moment to three seconds' duration; this causes not more than a white film similar to the effect of nitrate of silver, in the treatment of Desormeauux. The *modus operandi* is as follows: The instrument is connected with the electrode wires, which are then attached to the battery. The fluid in the cells must be of the right standard, and all the machinery in perfect order. When all is ready, I invariably let the cells down and try the instrument with a short flash. No matter what assurance I have of the perfection of the appliances, this little experiment excludes any possible failure. The prostatic portion to which the cautery is to be applied must have been ascertained, and the distance from the meatus measured. This distance is then marked on the instrument by a small rubber band. The patient, according to his preference, may stand erect, be on an operating table or in bed. The instrument is then introduced so that the fenestrum with its platinum wire is in contact with the part to be cauterized. The operator will know by touch when the instrument is in the right place, and the measure will corroborate the correctness of the situation. One hand holds the instrument and the other sets the battery in motion, and then touches the little spring to connect the interruptor, a flash follows, the finger disconnects the current. In one moment the operation is done, and the instrument is withdrawn. It causes no pain, and in some instances the patient scarcely believes that anything has been done. He is able to walk about and is not detained from business. In cases of very irritable patients, I have used cocaine injections, but it was scarcely necessary. The séance should be repeated in about three days, or even in two. The

instrument must be kept scrupulously clean, as the cautery will fail, if there is dirt between the connections.

The question now arises, how does this method bring about a cure? The end sought is, first to remove the obstruction, so that the bladder can discharge all the urine, and at regular intervals; and then, in order to make the cure radical, to reduce the prostate to its normal size. The theory is that the cautery first acts as a tonic and next as an astringent; the mucous lining shrivels up, the glandular tissue contracts, and by shrinkage the size is diminished. The stimulation gives new life and healthy action. Each repetition of the operation acts similarly, and perhaps on another part of the hypertrophy. The operation must be continued till the cure is effected. Care must be taken not to over-stimulate, and cause prostaticorrhœa, prostatitis, etc., thereby creating or aggravating the very ailment we seek to cure. The cautery must be given just severely enough to accomplish the object and no more. If the cauterization is too prolonged, and too deep, the glandular action is overtaxed and weakened and will be followed by a terrible prostaticorrhœa, which takes a long time to cure. At the same time an inflammation is created, which causes pain and swelling, and at last, the too greatly cauterized tissue will slough away and may cause septicæmia.

For these reasons, I prefer the slow method described, and am opposed to rapid methods, or too deep cauterizations.

The practical workings I judge by analogy, from observations of the cautery in hypertrophied tonsils. Great similarity of anatomical structure exists between the tonsils and the prostatic gland—both are glandular organs, covered by mucous lining, having epithelium; both are secretory organs, having ducts, follicles, canals, and one twelve to fifteen orifices and the other twelve to twenty small excretory ducts. In hypertrophy of the tonsils, after other remedies had failed, I succeeded by using galvano-cautery with this same instrument. The application was made in cases of children of very tender age, who stood free before me, and without any aid or force opened the mouth, and went through the operation without flinching. Not one complained of pain, all came back to have the cautery repeated, and then stood still with more confidence than at first. In these cases the immediate effect was a splendid illumination of the whole buccal cavity, and a white film was seen on the tonsil after withdrawing the instrument. The cautery could be repeated in two or three days; in one case it was done the next day. Sometimes the cautery was repeated in the same place, at other times, from preference, an adjoining place on the tonsils was selected. Almost daily observations of this series of cases convinced me that the galvano-cautery acted practically just as I have theoretically described. The patients were benefited, the tonsils diminished in size, and a cure effected. It was remarkable how soon the mucous lining regained its normal color, and when a deeper cauterization was used, there was no unpleasant slough, only a patch was observable, like in appearance to follicular ton-

illitis. The instrument was well adapted for the tonsils, the curve suited exactly, the fenestrum could be held against the exact place to be cauterized, without possibility of burning any other part by accident.

In treatment of the enlarged prostate by galvano-cautery, it is absolutely necessary to pay attention to other symptoms and troubles of the patient, according to established principles. Pain must at all hazards be allayed; this I generally accomplish by rectal suppositories. Chas. Mitchell, of Philadelphia, prepared for me some gelatine articles which act very well. In medication I rely mostly on belladonna. The bowels must be kept regular, since constipation adds considerably to the inflammation, and by pressure causes pain. While the galvano-cautery is used, it is of the greatest importance to attend to the state of the bladder by drawing off the urine and washing the bladder out.

Another possible method, which I call the *rapid*, consists in the destruction of the obstructive part of the prostate in one séance. This is done by holding the cautery on the offending part till the cautery has burned it down and made room for the passage of the urine. The objections to this method are the immediate shock, followed by pain and inflammation, which generally cause a new obstruction, partly by spasm of the bladder and partly by the debris of the destroyed gland. There is even danger of septicæmia. At best the patient is kept in bed, in pain and anxiety, for a long time. Prof. Bottini, of Pavia, practised a similar operation with ultimate success. He constructed his own instrument, and kept up the cautery forty-five seconds. The patient was kept in bed afterwards, and on the twenty-fourth day for the first time passed water voluntarily. It took six months before he was cured. While I admire the zeal of Bottini, I scarcely think his method will become popular.

Another method is the *radical*. It consists of perineal section, and at the same time the total destruction of the hypertrophied part of the prostate by galvano-cautery. This can be done with my instrument, either per urethram, per perineum, or by a larger galvano-cautery burner, or by the galvano-sling. The after-treatment consists in diligently washing out the bladder, using disinfectants, and keeping a catheter in the perineal wound. I would not hesitate to perform this latter operation, if indicated; that is, if the patient had no other chance, if it would be a risk to wait for any other procedure, and particularly if the case is complicated with strictures and consequently too violent spasms of the bladder.

A few days ago a man came under my observation, in whose case this operation would have been the only rational procedure. He had several strictures, admitting no larger sound than a No. 11 French scale, he had a calculus in the bladder, a perineal fistula, and hypertrophy of the prostate; was weak, in pain, and run down constitutionally. With such complications perineal section is the only known rational operation; in fact, no other would fulfil the indications.

Galvano-cautery has advantages over the knife, it

avoids hæmorrhage and leaves no raw surface to heal. The cautery protects the amputated surface with a scab, under which the healing process takes place.

Other Uses of the Instrument.—Though my instrument was constructed for the prostate, it has done good service in other diseases, which I will briefly mention.

Spermatorrhœa.—This disease is rare, but one genuine case was treated by applying the cautery to the ejaculatory ducts at $6\frac{3}{8}$ inches from the meatus. The applications were repeated once a week.

Impotence.—In several cases the galvano-cautery was applied to different places, such as prostate, Cowper's glands and ejaculatory ducts. The treatment was aided by other means.

In diseases of the bladder the instrument has worked admirably, particularly in villous tumor with hæmaturia, and in traumatic ulcer of the neck of the bladder. The patient had been injured, and a ragged wound near the neck of the bladder was transformed into a chronic ulcer. The place could be felt by the introduction of the instrument, the patient himself could give the best information when any instrument came in contact with the ulcer. One patient, weakened by years of constant hæmaturia, passed no bloody urine after the first application of the cautery.

Urethral granulations, denuded surfaces, and ulcers readily yield to the galvano-caustic treatment. Frequently patients present themselves to be treated for a chronic discharge, some call it leakage. I consider it error to assert that all chronic discharges of the urethra spring from strictures. On the contrary, I often find that when strictures are radically cured, the old troublesome discharge remains.

For twenty years I have treated such cases by local application through the endoscope. Generally we find chronic granulations, which yield to local, circumscribed applications of nitrate of silver, repeated at intervals. Sometimes we find denuded surfaces, which bleed at touch, sometimes chronic congestions, and even ulcers. With these affections the galvano-caustic has done better and cured quicker than the old method. The endoscope is needed to diagnosticate and locate the diseased spot.

Dr. Louis Sass treats *urethral strictures* by galvano-caustic, with an instrument he himself constructed.

I reiterate, my instrument was designed expressly for treatment of the enlarged prostate. I have used it since October, 1885. During those six months of use it fulfilled its purpose, and was useful in a variety of other diseases as stated. Detailed clinical histories of cases are not now given, for many reasons. Six months' work with a new instrument does not warrant in alleging an established method, or in giving reliable statistics or forming undeniable conclusions.

While the instrument has so far given me satisfactory results, yet more time is needed for observation, in order to give accurate statements and form fixed opinions. The time here allotted for reading a paper excludes a more extended statement. I hope that in the future I shall be able to complete the statistics of my new method.

The sole object of this paper is to introduce and

explain to the profession my new instrument, and to establish my method of treatment of hypertrophy of the prostate.

68 W. 35th St., New York, May, 1886.

OPERATIONS ON THE DRUM-HEAD FOR IMPAIRED HEARING; WITH FOURTEEN CASES.¹

BY SETH S. BISHOP, M.D.,

OF CHICAGO.

ATTENDING SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, AND TO THE SOUTH SIDE FREE DISPENSARY.

I will not occupy the time of the Section with a historical account of this operation, although it is replete with interest. Those facts only will be presented which are necessary to an intelligent study of this group of cases. The subjects for operation were not selected with a view to the promising nature of their cases. This method would have been more brilliant but less scientific.

If I have erred at all it has been in the opposite direction. For the purpose of making a crucial test of the efficacy of this procedure, I have made it the last resort in those cases which afforded no hope for relief from any other treatment. Perhaps the propriety of operating on these patients that seemed to promise no results might be questioned, were it not for the facts that in nearly all of them there was an unexpected improvement, and that no unfortunate consequences followed the operation. The cases I have chosen to operate on were far more hopeless than those with chronic suppurative inflammation. The consideration that the former respond so little to our efforts, while the latter are so amenable to treatment with inflations, cleansing, peroxide of hydrogen, boracic acid, bichloride of mercury, etc., with the result of not only arresting the disease, but of improving the hearing, has led me to seriously contemplate the advisability of establishing the suppurative process in proliferous inflammation of the middle ear. In but three cases in my practice has this condition followed the procedure under discussion, and I have operated more than one hundred times. It happened while I was preparing this paper. A temporary purulent discharge occurred immediately after the operations. It had the effect of keeping open the apertures, and no evil consequences followed.

In choosing the location for the incisions I have usually given preference to the section of membrane anterior to the handle of the malleus, in order to avoid the possibility of wounding the carotid artery, should the bony wall of the carotid canal be deficient, or of penetrating the labyrinth through the fenestra ovalis.

Cocaine in a four per cent. solution was employed as a local anæsthetic in very sensitive individuals. It allows sufficient deliberation on the part of the operator, for patients experience no actual pain, although they feel the knife.

Chronic non-suppurative inflammation of the middle ear existed in all of the following cases.

Case 1.—Male, 43 years old, on Board of Trade.

Said he had not been able to hear with the right ear for many years. He consulted me relative to a sudden attack of sub-acute inflammation of the left middle ear and Eustachian tube. The right drum-head was thickened, opaque, and retracted. The handle of the malleus was fore-shortened and the processus brevis prominent. There was no hearing for the watch even by bone conduction, but the tuning-fork could be heard by aerial conduction close to the auricle. I advised him to submit to an operation; but as he had no hope of receiving any benefit for his worse ear, and requested me to direct my efforts toward the better ear only, to save what hearing he had, I contented myself at first with the ordinary treatment addressed to both ears. The left ear improved rapidly, while the right remained unaffected. Before discharging him I instilled a warm four per cent. solution of cocaine into his right ear, and at the expiration of twelve minutes made a free opening in the anterior half of the membrana tympani, with Politzer's paracentesis knife. He was not conscious that any cutting was done, and gave no evidence of any unpleasant sensation, except by the remark that "The funnel seemed to press against the ear." The immediate result was that he heard my watch on contact with the auricle, and the tuning-fork five inches distant. He said it was the first time in many years that he had heard a watch with that ear. April 29th he could still hear the watch with that ear.

Case 2.—Deaf mute, German farmer boy, 19 years old, came under treatment in September, 1885, during my service at the Illinois Charitable Eye and Ear Infirmary. There was no sign of any perception of sound either by aerial or bone conduction with either ear. I placed him on a course of treatment addressed to both the middle and internal ears. For the former I employed catheterism at first, and the Politzer method later, as the Eustachian tubes became more pervious. For the purpose of imparting tone to the auditory nerves, I employed central galvanization daily. After four months of persistence in these methods, the only apparent improvement was his ability to hear the tuning-fork as it vibrated in contact with the mastoid process of the right side. I repeatedly tested his hearing in the presence of others, but he was unable to hear loud clapping of hands immediately behind the auricles.

January 28th I opened both drum-heads, leaving elliptic perforations which remained open two or three days. My record book shows the immediate result to have been as follows: Patient hears the loud voice through the conversation tube, but does not understand words. He makes an effort to reply, but the result is only unintelligible gibberish. In speaking to him through the tube, care is taken to prevent him from watching the lips, for he has acquired some proficiency in lip-reading. He repeats the vowel sounds with more or less accuracy, and if given an opportunity to watch the relative positions and movements of the lips, tongue and teeth, he reproduces the sounds with surprising fidelity.

February 1st, the aperture having closed, I opened the right membrane. Patient hears ordinary conversational tone through the tube, repeating words.

¹ Read in the Section on Ophthalmology, Otology and Laryngology, at the Thirty-Seventh Annual Meeting of the Am. Med. Association.

February 8th, made long openings in both membranes. I have taken pains to exercise the auditory apparatus by using the vowel sounds and the powers of the consonants separately. He says he hears better with both ears, and seems to appreciate various sounds with greater nicety than before.

February 11th, 17th, and 27th, opened both drum-heads. Patient says he hears my watch on pressure with right ear, and imitates the ticking. He hears the fork close to the right meatus. At the last operation I made two incisions in such a manner as to leave triangular openings. I waited nearly a month before operating again, continuing the inflations and galvanization. The perforation on the left side had then closed, but on the right it remained open.

March 25th, made long aperture in both drum-heads. Hears watch on contact, and fork one inch, with right ear.

March 30th, operated on both drum-heads, making two incisions in each, so as to embrace large triangular portions of the membrane. He is now able to construct and utter sentences of considerable length quite intelligibly.

Encouraged by the improvement in the preceding case, I adopted the same course of treatment in the following one. It is in striking contrast with the first, and illustrates the impossibility of predicting results.

Case 3.—Farmer, 25 years old. December 11th, 1885, said he had been losing his hearing for "a number of years." There were evidences of disease of the labyrinth, but no syphilitic history could be elicited. Neither the watch nor fork was heard by bone conduction with either ear, but he could hear the fork one inch from the right meatus. There had never been any tinnitus aurium. His treatment was exactly the same as in Case 2. Central galvanization and inflations failing to accomplish anything for him up to January 27, 1886, I opened the right drum-head, with no result.

February 3d, operated on the left one, with no improvement.

February 12th and 17th, and March 4th, operated on both drum-heads. When I discharged him he said there was no perceptible change of any kind in his condition.

Case 4.—Brought for consultation by Dr. Bennett, from Richmond, Illinois, on February 5, 1886. The patient was a young woman 19 years old, and had suffered for "several years." The tympanic membranes were thickened, opaque and retracted. She could not hear the watch, and could hear the fork only when in contact with the mastoid process. Symptoms were present which pointed strongly to labyrinthine disease. No satisfactory results had attended the ordinary treatment. I made free openings in the drum-heads with the immediate result that she heard the fork at a distance of ten inches from either ear. The patient returned home with her physician, who promised to keep a record of her case and report the results to me.

March 23d I received a letter from Dr. Bennett in which he stated, after referring to my operation, that "Since then I have punctured one drum-head twice

and the other once. She seemed better after each puncture, but now has reached a stationary period where she does not improve. I am inflating the middle ear with the catheter once a week, and applying the galvanic current. What would you further advise?" etc.

Case 5.—Cooper, 36 years old. Has had great tinnitus in both ears for two years. The drum-heads were opaque, thickened and retracted. Hearing for the watch was on pressure for the right, nil for the left. Fork was heard one-fourth inch from the right ear, and on contact with the left mastoid process. After the operation he could hear the watch two and one-half inches, and the fork ten inches with the right ear, the the watch seven inches with the left. The tinnitus ceased in the right ear and diminished by seventy-five per cent. in the left.

Case 6.—Woman, æt. 42. Has suffered greatly from noises in both ears. Heard watch on contact with the right ear, and on pressure with the left.

February 18th, opened both drum-heads. Watch was heard two inches from the right ear. Hearing remained the same as before in the left, although she thought it was better. The tinnitus, which was increasing before, now intermits, and is less annoying.

February 20th, hears watch two and one-half inches from right ear. Hearing unchanged in left ear. Tinnitus diminished in both.

February 27th, hearing distance for watch on right side, a little more than five inches. No change in left ear. Tinnitus less in both. The improvement in the hearing distance for the right ear was more than 500 per cent.

Case 7.—Woman, 50 years old. Proliferous inflammation of long duration. Hearing for watch on right side, nil, on left side, pressure; for fork on right side, one-half inch.

March 28th, opened both drum-heads; immediate result, nil.

March 29th, both apertures remain open. Hears fork four inches from right ear, and watch on contact with left. The improvement in the right ear was 800 per cent.

Case 8.—A woman about 40 years old came from the country for consultation. She attributed her trouble to the use of quinine. Said she had taken it during a year for intermittent fever, which she had about fifteen years ago. Ever since then her ears have rung constantly. She had typhoid fever nine years ago. The group of symptoms were characteristic of proliferous inflammation. Hearing for watch was on contact for the right ear, one-eighth inch for the left. I opened both membranes, whereupon she heard the watch one-eighth inch from the right, and one-half inch from the left. The tinnitus had diminished.

Case 9.—Iron worker, 45 years old. Hearing of the right ear for watch, nil; for fork, at rim of auricle. Hears watch in left ear on pressure, and fork, one inch. Operated on right ear, with the immediate result that he heard the fork one-half inch distant. Two days later the hearing had improved so much that he heard the fork two inches from the auricle, and the snapping of the nails six inches.

Case 10.—Horseman, 50 years old, whom I had treated several months in the South Side Free Dispensary, by catheterism and Politzer's method, without any perceptible permanent improvement. The drum-heads were greatly thickened, and densely opaque. The manubrium was much foreshortened, and there were cretaceous deposits in both membranes. As in many such cases, there was a chronic naso-pharyngeal catarrh which was quite intractable. There was absolutely no hearing for the fork or watch. The disease had evidently invaded the labyrinth. Although there appeared to be no reason to expect any improvement, since I had never witnessed any ill consequences following the operation, I opened both drum-heads. It was like cutting through leather, so thick and hard and tough were the membranes. The chalky deposit imparted a grating sensation to the fingers that held the knife. He strongly insisted that the operation not only improved his hearing, but relieved the uncomfortable sensations in his head. No later history was obtainable.

Case 11.—Laborer, 51 years old. Had tinnitus of long duration. There was inspissated cerumen in the left meatus when he presented himself at my clinic at the Infirmary in July, 1885. Hearing for the watch then was one-fourth inch for the right ear, and pressure for the left. After eight months of the usual treatment the hearing distance had increased by four times the original distance in the right ear, and from bone to aerial conduction, at one-half inch distance, in the left. But there it remained without further progress until March 29, 1886, when I opened both drum-heads with triangular apertures. Immediately the hearing distance was increased in the proportion, in the right ear, of two to seven, and in the left ear it was doubled.

Case 12.—Man, 27 years old. Had a fall when four years old and alighted on the left parietal eminence. Says he has been deaf in the left ear ever since. Has had noises in both ears for eight years. Inspection revealed proliferous inflammation in both middle ears, and I strongly suspect that there had been a fracture of the temporal bone, extending through the left tympanic cavity. There was no hearing for the watch, and the fork could be heard only when vibrating loudly on either mastoid process. I made large openings in the drum-heads, whereupon he could hear the fork by aerial conduction one and one-half inch from the right ear, and one inch from the left. The tinnitus remained undiminished.

Case 13.—Old soldier, 54 years of age. His affliction dates from the battle of Pittsburgh Landing, where he was precipitated by the explosion of a shell. Thus his disease is over twenty years old. There was no hearing for the fork. The inflammation was of a proliferous type, and the auditory nerves were diseased, beyond a reasonable doubt. There were noises in both ears. As there was no improvement from the usual treatment, I opened both drum-heads, merely to see what the result would be. It seemed to have no effect on the right ear, except to diminish the tinnitus, but he was able to hear the fork close to the tragus on the left side. Four days later the tinnitus had ceased, and the hearing remained the

same for the fork. He repeatedly assured me that he could hear better, and said his "head felt clearer and better" for the operation. He said he could hear some with the left ear. I doubt it. I saw the patient several times subsequently, and to my surprise, when I last saw him, he retained the improvement he had made.

Case 14.—Swedish workman, 35 years old. Had tinnitus one and one-half year in the right ear, and two and one-half in the left. No hearing for watch. Fork heard one-half inch from right, and one-eighth inch from left ear.

March 29th.—I made large openings in the membranes, after which he could hear the watch on contact with the right ear, but not with the left. Hearing for the fork was increased just fourfold for both ears. The tinnitus was diminished.

March 30th.—The hearing was five times better in the right ear, and eight times better in the left, than it was just after the operation, and the tinnitus was further decreased.

April 22.—Hears watch one inch with the right ear, and on contact with the left. Tinnitus is diminished by one-half in the right ear, but remains the same in the left. I operated on both ears again, whereupon the hearing was less acute, and the tinnitus was diminished.

April 29th.—Hearing for the watch was one-half inch for the right ear, and contact for the left. There was slight tinnitus in both ears.

The watch employed for testing the hearing can be heard sixty inches by the normal ear, and the tuning-fork is of ordinary size, pitched at a above middle c .

In recapitulating it will be observed that only two out of these fourteen cases were under 25 years of age. One of these was a deaf mute and the other presented symptoms of labyrinthine disease. All except two of the remaining twelve were 35 or older. Four were 40 or more, and four were 50 or over. The average age was above 38 years. It should not be forgotten that the conditions for which these operations were performed were among those generally regarded as the most hopelessly incurable that ever confronted an aurist. Notwithstanding this, thirteen out of the fourteen cases were more or less benefited, and some were improved by not less than 500 and 800 per cent. How permanent this improvement may prove to be remains for the future to determine, I give the facts as far as they are in my possession.

The history of these cases has been brought down to as recent a date as the nature of circumstances would permit. I have examined and operated on some of them within the last week. I have had as yet no reason to regret the operation, and in some cases of this group, as well as in others which there is not time to report at this meeting, the improvement has been greater than I was prepared to expect. I shall follow up the history of all cases as far as possible and record remote results. My object in operating was to cause cicatrices in retracted drum heads, for the purpose of restoring their normal tension through contraction of the cicatricial tissue. But when the loss of hearing seemed to be due largely

to the interposition of a thick, dense, unyielding drum head between the source of sound waves and the perceptive apparatus, I attempted to maintain a permanent aperture.

In conclusion I must say that the happy results obtained in the majority of cases in which I have operated, and the fact that no ill consequences have followed the operation, have convinced me that the procedure is advisable in the class of cases I have selected. It improves hearing, and sometimes relieves distressing noises and other subjective symptoms when nothing else will.

719 W. Adams St., Chicago.

MEDICAL PROGRESS.

BADAL'S OPERATION, OR LACERATION OF THE INFRA-TROCHLEAR NERVE FOR THE RELIEF OF GLAUCOMA.—DR. J. S. PROUT, of Brooklyn, in an article on this subject says: The laceration (*arrachement*) of the infra-trochlear nerve (*nerf nasal externe*) has been proposed by Badal, of Bordeaux, for the relief of ciliary pain from various causes, among them any pathological condition that may induce hardness of the eyeball.

In order to find it we need only to lay the index finger, palmar surface forward, on the globe immediately below the brow, the extremity of the nail resting on the side of the nose; the upper half of the free margin of the nail will then cross its course as it emerges from the orbit. It and its accompanying arteriole may often be felt as a very small soft cord about half way between the pulley and the upper margin of the tendon of the orbicularis muscle. A curved incision three-fourths of an inch long, as indicated by the position of the finger nail, will suffice for its exposure. It is small, soft, not readily distinguished from its surroundings and may easily be divided in the search for it, but fortunately it is not necessary to carefully isolate it. After having cut through the integument and the muscular layer the subjacent connective tissue may be separated by two strabismus hooks, one of which is then to be passed under the nerve and its accompanying arteriole from below upward, scraping the periosteum, *on which it lies*, as one takes up the tendon in a strabotomy. The tissue on the hook is lacerated by pulling with a very moderate degree of force directly forward. Half an inch of the nerve may thus be drawn out and afterward cut off. The hæmorrhage from the ruptured arteriole is slight and easily controllable. The wound is to be closed by sutures, and any simple dressing applied that will keep the lids quiet. Except cleanliness "antiseptic precautions" are not necessary. Healing is almost always by immediate union. In forty-eight hours the sutures may be removed. In some cases small tender nodules have remained after healing was complete.

Badal at first used chloroform, as he carefully isolated the nerve, but in his latter operations he used no anæsthetic, as the time required is very short and

the pain sharp only when the nerve is ruptured. How the laceration of this nerve reacts on the nutrition and sensation of the eye, Badal does not attempt to explain, but refers to the well-known fact that such operations practised on the peri-orbital nerves do exert a therapeutic action not only against the symptom pain, but also against vaso-motor and secretory disturbances. Besides, it does not matter to the surgeon whether it is by a direct action on the nerve or by a simple reflex action. It is not enough to *cut* the nerve, it must be *stretched and torn, lacerated*, so that the action, if a direct one on the tissue, may be propagated backwards as far as possible in the line of the nasal nerve. In his last paper Badal gives his clinical results based on eighteen patients with glaucomatous disease, on whom he lacerated the infra-trochlear nerve twenty times. They were not selected cases. At first iridectomy, sclerotomy and laceration were done somewhat indifferently, but the last-named operation was done on all his later cases. He calls especial attention to the fact, as one of its decided advantages, that this operation, as it does not attack the globe of the eye, is accepted much more willingly by the patient than iridectomy or sclerotomy. Four consented to an operation only on a formal promise that the eyeball should not be touched.

He says it has never aggravated the condition of the patient, and, without exception, the laceration of the nerve has relieved the pain, often immediately; some patients have suffered until the next day. An operation not involving the eyeball could not be expected to cause a rapid diminution of the tension, and in this particular it is inferior to sclerotomy or iridectomy, but in some cases the tension did diminish quite rapidly, in others slowly, in some no effect was produced. In cases where it has failed no better result has been obtained from iridectomy or sclerotomy done later. On the other hand in a number of cases where these operations had given no results, laceration had succeeded. Abadie has proposed to combine it with one or other of them, but Badal thinks that in severe cases, when a delay of only a few hours may be followed by total loss of vision, a paracentesis of the cornea will relieve the tension, which condition the laceration will then maintain. As far as he can judge it has a value in improving vision at least equal to the other operations.

These are the results of his twenty operations on eighteen patients (nearly all of whom were unpromising for any operation): *Pain* was relieved at once in ten, rapidly in one, gradually in five, not stated in four. *Tension* was relieved quickly in four, gradually in eight, not relieved in six, not stated in two. *Sight* had long been lost in seven, was improved in four, not stated in five.

At the meeting of the Ophthalmological Society of the United Kingdom of April 8, of this year, Mr. Spencer Watson reported that he had trephined the sclera in a case of hæmorrhagic glaucoma. Mr. Brailey said that in such hopeless cases, the best treatment was to stretch the *supra-trochlear* nerve. Mr. McHardy spoke of the ease with which the *supra-trochlear* nerve can be found in the living subject. Mr. E. Browne in two cases had obtained no dimin-

ution of tension from stretching the *supra-trochlear* nerve.

As the *supra-trochlear* nerve is a branch of the *frontal*, and, consequently, much less directly connected with the nervous supply of the eye-ball than the *infra-trochlear* and no more easily found or operated on, it is difficult to see why it should be chosen for *stretching* in preference to the latter.

I have performed laceration of the *infra-trochlear* nerve nine times on five patients, all so unpromising that the very small chances of success from any operation on the eyeball did not seem worth the risk that would be run. The first four operations were done under ether, the others without anæsthetic, except that in the ninth a solution of muriate of cocaine was injected at the location of the wound. In this case there was no complaint of pain. The third patient complained but little, but the fourth complained of sharp pain when the nerves were torn. In this my experience agrees with Badal's, who says that the operation is so slight and so quickly done that anæsthetics are unnecessary.—*American Journal of Ophthalmology*, July, 1886.

SYPHILITIC CHOREA.—A young man in Buenos Ayres, who by his strange contortions had excited the curiosity of the passers-by, recently came under the care of Dr. FRANCESCHI, who was somewhat puzzled by the symptoms. The movements were of a choreic nature, the most characteristic being a contortion of thoracic abdominal and pelvic muscles. The patient's condition became so grave that he could not move out of his room. For a month various methods of treatment were unsuccessfully employed—electricity, sulphur baths, strychnine, hyoscyamine, etc. A consultation was then arranged with Drs. Valdes and Alcorta. The first of these gentlemen remembered having treated the patient six months previously for a chancre, which at the time was not thought to be syphilitic, and had not been treated by mercurials. There were no enlarged inguinal glands or other marks of syphilis; however, it was decided that the chorea might be of syphilitic origin, and therefore Ricord's pills (green iodide of mercury), inunction over the spine of a mercurial and croton ointment, together with Van Swieten's solution (perchloride of mercury) and vinum ferri, were prescribed. In three days salivation occurred, and simultaneously with it the choreic convulsions disappeared. The mercurial treatment was then discontinued, but it was found necessary to resume it, for the convulsions soon began to recur. The salivation subsequently became so distressing that the mercury was again stopped, and the convulsions returned, though not so severely as before. Mercurial and iodide treatment was continued for six months, at the end of which time the patient was completely cured. Dr. Franceschi considers this case especially instructive, as though various predisposing causes are usually named in connection with chorea, neither syphilis nor mercurial treatment is mentioned, as far as he can find, by Bouchut, Graves, Jaccoud, Diday, Tardieu, or Trouseau. It has, on the contrary, been stated that mercurialisation may act as a factor in

its etiology; here, however, is a case in which mercury cured it. The author seems to think that perhaps a hereditary syphilitic taint may sometimes have some effect on the development of chorea, and that, if so, mercury would be the best form of treatment to adopt.—*Lancet*, July 31, 1886.

URETHAN AND CHLORAL IN TRAUMATIC TETANUS.—MR. WM. THOMAS JACKMANN gives the following brief notes of a case of tetanus which recovered under the influence of the new hypnotic, urethan, in conjunction with chloral hydrate:

J. C., a lad aged 15 years, came under my care on March 15, 1886. The patient presented well-marked symptoms of tetanus, which were evidently the result of an injured finger on his right hand. This had been crushed by clogged wheels five weeks previously, and had healed up slowly under simple local treatment. The lockjaw was complete, and the episthotonus well marked; severe paroxysms of pain were complained of, which were greatly exaggerated at night. The patient had noticed his neck and jaw muscles gradually becoming stiff for the past few days, but attributed this to a chill. Chloral hydrate in 20-grain doses every three hours was ordered. This relieved the paroxysms of pain slightly during the day, but the lockjaw, episthotonus, and rigidity of the muscles of the legs remained the same, and the pains were just as severe and frequent during the night. Fluid nourishment was administered and the chloral treatment continued until March 25, when, as no abatement of the symptoms were apparent, after consultation with my partner, Mr. T. Simpson, it was decided to discontinue the chloral during the night, and in its place give the patient four grains of urethan every two hours, from 6 P.M. to 6 A.M. The first night of this treatment showed a marked decrease in the severity of the symptoms, and the patient made gradual and uninterrupted progress until April 20, when his recovery was established. The failure of the chloral hydrate to relieve the severe symptoms during the nights, and the well-marked improvement under the influence of the urethan, seem to point to the latter being likely to prove a very valuable drug in the treatment of tetanus, either prescribed alone or as above in conjunction with chloral hydrate.—*Lancet*, June 12, 1886.

EFFECT OF SUBCUTANEOUS FRACTURES ON BODY TEMPERATURE.—E. MÜLLER has recorded the rectal temperature in 36 cases of uncomplicated fractures, and found, in opposition to the observations of Maas, a rise in temperature in 35. The maximum was usually reached on the first or second evening, and was maintained for from one to thirteen days. Neither the age of the patient, the amount of extravasation, nor the extent of the fracture appeared to influence the extent of the rise in temperature. Müller has collected all the records of uncomplicated fracture (English, German, and American) at the time available to him, and finds that out of 359 cases, 308—85 per cent—passed through with marked rise of temperature.—*Centralblatt f. Chirurgie*, June 12, 1886.—*Medical News*, August 14, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, AUGUST 28, 1886.

SCARLATINAL NEPHRITIS.

It is a striking coincidence that the two most important contributions on the subject of scarlatinal nephritis that have ever appeared in this country were published within a few days of each other; the one a chapter on the subject in DR. PURDY'S recent work on "Bright's Disease and Allied Affections," the other an article on the subject by DR. I. E. ATKINSON, of Baltimore, in the July number of the *American Journal of the Medical Sciences*. Of the various dangerous complications and sequelæ of scarlet fever none are more important, or more dangerous to immediate or subsequent life and health, than the derangements of the kidneys. A number of careful observers hold that the kidneys are always affected in scarlet fever; that nephritis is as essential a feature of the disease as is the rash of measles. However this may be it is certain that there is an enormous number of cases of nephritis arising from scarlatina, and it is a clinical fact that almost all fatal cases of scarlatina present renal symptoms.

It has been held that while a very large percentage of cases of scarlatina present albuminuria, all these are not truly nephritic. It is not necessary to claim that each case of albuminuria arising in the course of scarlet fever is due to an actual nephritis, but it is certain that a very large number of the cases of so-called pyrexial albuminuria occurring in scarlet fever are nephritic, and accompanied by nephritic lesions. There are cases also in which nephritic lesions are found at the autopsy, though albumin may not have been present during life. To still further show the importance of the subject, we have no means of knowing the particular cases of scarlet

fever which are most likely to be accompanied or followed by nephritis. Various symptoms have been pointed out which were supposed to indicate that the kidneys were or would be involved, but with the exception of those mentioned by Mahomed they seem to be valueless: he insisted that the nephritis of scarlet fever is preceded by increased arterial tension, constipation, and the presence of blood-crystalloids in the urine (which may be recognized by means of the guaiacum test). There are pathological reasons for supposing that future observation will probably confirm this statement. But it is not our intention to speak exclusively of those cases of scarlatinal nephritis which arise during the course of the primary disease, or which are already distinctly recognizable before the disease has passed off. There are some cases in which the primary disease has occurred years before, and has probably been almost forgotten by the patient or the family; the physician is called to treat a case of dropsy, which is ascribed to a transient disorder occurring but a short time before. Or it may be that the patient is suffering from cardiac hypertrophy with slight albuminuria, or he has albuminuric retinitis, and a careful examination will disclose a history of scarlet fever as many as ten or fifteen years previously. In these cases we must believe that nephritic symptoms occurred during the primary disease, but were unrecognized and have pursued a latent course until they have now passed into the chronic form. It will be seen, then, how necessary it is to continue treatment, and the most careful supervision over the patient, until all evidences of the disease have disappeared. And not only this; but no one should fail to keep a most careful watch over the kidneys in a case of scarlet fever, however mild it may be.

It is of the utmost importance that every case of scarlatina be treated with a view of preventing renal complications; this should be done from the beginning of the disease. The urine must be examined daily in every case, especially during the second, third and fourth weeks; it is not sufficient to examine for albumin, but evidences of renal disease must be watched for with the microscope—for, as has already been said, renal disease may be present though albumin be temporarily absent from the urine. When nephritis is present the urine contains renal epithelium, casts, and generally some blood corpuscles, the casts being cylindrical, hyaline, or epithelial. This examination should include a portion of the whole urine passed during twenty-four hours. It seems scarcely necessary to go into the refinements of chemical and microscopic examinations in these

cases, except to determine if possible the extent to which the kidneys are damaged; for when renal epithelium, casts, blood corpuscles, and possibly albumin are found in the urine of a case of scarlatina we need scarcely hesitate as to the diagnosis. It would be well also to take a sphygmographic tracing of the pulse regularly, if for no other purpose than to determine the correctness of Dr. Mahomed's statement in as many cases as possible. In cases in which the scarlatina has been overlooked on account of its mild character there may be doubts as to the form of the renal lesion present; in these cases much may be done by obtaining a history of recent scarlatina in the family or the vicinity, and by careful examination of the patient for evidences of desquamation or of recent sore throat.

The fact that scarlatinal nephritis is of rare occurrence in the first year of life seems in a measure to give at least one indication for treatment, since it is in this year that the patient's food is almost exclusively milk. Jaccoud said about a year ago that for fifteen years he has not had a case of nephritis among his scarlatinal patients, and he attributes this to his exclusive milk diet. It should be used from the beginning of the attack until the end of the fourth week. The patient should be carefully protected; Mahomed declared that a slight chill during convalescence is sufficient to cause albuminuria. Daily baths or tepid sponging should be practised during the height of the disease, and by this renal complications are frequently avoided. In the mildest cases the patient should be kept in bed for at least a week after the fever has subsided: and he should not be permitted to leave the room before the end of the third week. During convalescence the daily tepid bath or sponging should be practised until desquamation is completed, as a measure of precaution against the spread of the disease. Active purging is unnecessary, but it should be remembered that a condition of constipation may raise the blood pressure and hasten renal inflammation; and Mahomed held that the failure of the bowels to move on a single day was sufficient to cause high arterial pressure and its results. Certain authors recommend the internal administration of chlorate of potash and salicylates in scarlet fever; they should not be used, nor should any drug be given which is known to be a renal irritant. With the first symptoms of renal trouble we should begin the administration of digitalis, as there can be no doubt that it is the most powerful drug that we possess in dealing with scarlatinal nephritis. Other useful diuretics are the citrate, acetate, bicarbonate and bitartrate of potash. Dr. Atkinson espe-

cially recommends a lemonade made by adding one drachm of cream of tartar to a pint of boiling water into which a lemon, cut into thin slices, has been dropped. This quantity, properly sweetened, may be taken by a child 5 years old during the day. Pure water is also an efficient diuretic, and may be given freely. It is in the anuria, or threatened anuria, of scarlet fever that the alkaline salts are most useful. The convoluted tubes are now blocked up with colloid matter, and as colloid matter is dissolved when brought in contact with an alkaline solution, the indication is clear. The salts of potash formed with vegetable acids are most desirable in this case. The salts of sodium are less efficient than the potash salts, but in some cases they may be used with advantage, especially when it is desirable to render the urine alkaline for a considerable time. Here the acetate of sodium or the effervescent citro-tartrate of sodium may be used. More pleasant than these, and equally efficacious, it seems, are the granular effervescing citrate of potassium and citro-tartrate of sodium, and citrated kali.

Attention should be paid to the proper action of the skin. The hot pack, wet or dry, is very useful; but care is demanded that sudden chilling do not occur. In cases of threatened uræmia jaborandi or pilocarpin will often prove useful; but one must not forget the effects of these drugs on the heart, and the danger of inducing collapse. Should uræmic coma or convulsions occur they should be treated without reference to the primary disease. It seems necessary to say that the most efficient means of treating uræmic convulsions is by the subcutaneous use of morphine; it is very much more efficient than chloral in uræmic convulsions from any cause. It is not, as many suppose, dangerous to life. The cardiac complications in scarlatina should receive prompt attention. When the area of cardiac dulness begins to extend, the second sound becoming more accentuated, and the apex impulse changing its position digitalis should be administered. Should the symptoms of hypertrophy continue it as well to add convallaria to the digitalis; the fluid extract of the leaf in three to ten drop doses. There is reason to hope that in those grave cases in which hypertrophy has passed into dilatation we have an efficient drug in strophanthus, which is a more powerful and rapid cardiac stimulant than digitalis; but it is unsuitable as a substitute for digitalis in the general treatment of scarlatina. Its action seems to be wholly on the cardiac muscle, it having little or no action on the arterioles. It will aggravate rather than be of service in those cases in which nephritis is very acute, and the urine very bloody.

PASTEUR'S ANTI-RABIC INOCULATIONS.

Notwithstanding the apparent successes of Pasteur's anti-rabic inoculations there still seems to be a great deal of scepticism in the medical profession and among the laity. The medical journals have been diligent in supplying a hungry public, lay and medical, with the details of the performances of the eminent biologist, and the impressions produced certainly seem to be most varied. DR. GRANCHER, Pasteur's Assistant and Inoculator, has recently thought it proper to vindicate in a public lecture the character of M. Pasteur, which has been so much aspersed through the unseemly malignancy of his adversaries; and certainly no one is better qualified for the task than Dr. Grancher, who has been Pasteur's Assistant from the beginning of the inoculations.

After going into the diverse phases of the questions at issue, and the methods followed by Pasteur in his work, dating from the day of his communication, on January 24, 1881, to the Académie des Sciences on the saliva of a child which died from rabies in Lannelongue's wards, to the application on Meister, the first human subject of the experimental method which had succeeded so well on animals, Dr. Grancher also drew attention particularly to the objections made from different quarters to the method. These objections may, in reality, be reduced to two: 1. M. Pasteur treats his rabic patients with a product which is not rabic; this is the opinion expressed by English medical men. 2. The second objection (which is made by a large number of the French Faculté) is that the greater part of those inoculated had been bitten by dogs which were not rabid. The English medical men who composed the Commission appointed to investigate the subject went over to Paris, and, after having witnessed the inoculations at Pasteur's Laboratory, took back with them a rabbit rendered rabic by Pasteur's method. They inoculated another rabbit with its spinal marrow, and afterwards four dogs with the spinal marrow of the rabbit which they had inoculated. The dogs died some time afterwards with symptoms of evident rabies, which seemed to remove all doubts from the minds of the Commission. As to the doubts entertained by the French, Dr. Grancher replies by referring to the statistical report framed by MM. Chantemesse and Charrin, who have been lately appointed to Pasteur's Laboratory, and charged to analyze the cases of 1335 persons inoculated up to June 21st. The following considerations may be deduced from this report: Having in the first instance noticed persons bitten by mad dogs, whether the condition of the dogs was verified at the autopsy or that their

spinal marrow had determined rabies in another animal, or whether the symptoms observed permitted no doubt as to the malady, the authors found that of 96 patients belonging to the first category there was one death, or a mortality of 1.04 per 100, or 10 per 1000 in round numbers; and of 644 persons of the second category 3 died from rabies, a mortality of 0.46 per 100, or a 5 per 1000 in round numbers. These results comprise only those persons bitten before April 22; that is to say, when the disease was in full force. These statistics, compared with those of M. Leblanc, on Hydrophobia in the Department of the Seine, give an average mortality of 7.5 per 1000 instead of 160 per 1000. As to the 48 persons bitten before April 22 by mad wolves, they cited 7 deaths among them, or 14 per 100; but statistics established later show a mortality of 82 per 100 from bites of mad wolves. In an article in the "Dictionnaire Encyclopédique des Sciences Médicales," Dr. Brouardel gives a mortality of 67 per 100. Thus it is seen that the difference between the two results is very great.

In following up their investigations MM. Chantemesse and Charrin have established special statistics of results of bites in uncovered parts, such as the face and hands. Of 54 persons bitten in the face and hands before April 22, by dogs known experimentally to have been mad, there was one death, or a mortality of 1.8 per 100, or 18 per 1000. Of 400 persons bitten on the face and hands by dogs known clinically to be mad there were 3 deaths, or a mortality of 0.75 per 100, or 7.5 per 1000. In referring to the documents of the Council of Hygiene from 1862 to 1872, it is found that for bites of the face there was a mortality of 88 per 100, or 880 per 1000; and for those of the hands a mortality of 67.25 per 100, or 672 per 1000. In taking the average of these two groups, that is to say, in placing together the tables of bites on the hands and those on the face the result is 800 per 1000, instead of 18 and 7.5 per 1000.

Dr. Grancher has thought that it would be interesting to compare the efficacy of the three vaccinations in vogue: that of Jenner, that for charbon, and that for hydrophobia. Before the era of Jennerian vaccination, the non-vaccinated (non-inoculated) died from smallpox at the rate of 500 per 1000, those imperfectly vaccinated in the proportion of 260 per 1000, and those effectually vaccinated in the proportion of 23 per 1000. The veterinary surgeons who vaccinate for charbon have furnished the following statistics: Mortality before vaccination 120 per 1000; after vaccination an average of 5 per 1000. The statistics of M. Leblanc compared with those of

Pasteur concerning hydrophobia give the following results: Mortality before anti-rabic vaccination 160 per 100; after vaccination 7 per 1000. The prophylactic influence of these three kinds of vaccination is therefore evident; and, as M. Grancher remarks, the above facts fully reply to the objections made, and still more to the systematic negation of certain persons who build their arguments on a few isolated cases instead of examining the question as a whole.

Dr. Grancher gives some information as to the methods by which Pasteur obtains the attenuation of the rabic virus when it is submitted to dessication by contact with sterilized air. But since his earlier inoculations he has made certain modifications in his method, so as to simplify it as much as possible, and he has succeeded in being able to suppress the inoculation with the spinal marrow for the first three days. The rabbits to be inoculated are now chloroformed while being trephined and inoculated, and these operations are done with aseptic precautions as much as possible. The room is only slightly moistened with carbolic acid; if it were thoroughly washed out with the acid the virus would be destroyed. Now only ten inoculations are made, instead of thirteen as in the case of Meister, the first patient. They are made every two days, so that there is a day's interval after each inoculation. The first inoculation is made with a spinal cord that has been preserved fifteen days, the second with a cord fourteen days old, and so on; the last being made with a cord only six days old. He uses cords only from one to five days old for those cases in which the wounds from the bites are especially dangerous, either on account of the region bitten, the number of the wounds, or on account of the death of injured tissue.

CHEVREUL'S CENTENARY.

On next Tuesday M. CHEVREUL, "Doyen des Etudiants," as he calls himself, will be one hundred years old. He bids fair to be at that time, as he is now, in possession of sound health and unimpaired mental faculties, if we may judge by the fact that he now works nine or ten hours daily with the vigor and enthusiasm of a young man who has yet to win his reputation and fortune. He has a face that more properly belongs to the man of three-score than one hundred years, and a clear firm voice which has but little if anything of senile weakness. And there seems to be nothing to prevent his enjoying the celebration which will be held in his honor in his native place, Angers. There will be a procession, and a dinner and fireworks, a few speeches perhaps, and it

is not unlikely that the great scientist will tread a measure with some of the girls whose great-grand-fathers were his playmates.

His father was a successful physician in Angers, and noticing the early liking of his son for chemical investigation taught him carefully, sent him to the best school in Angers, and to Paris in 1803, when he was 17 years old. That was just nine years after the killing of Lavoisier on the edict "The Republic has no need for scientists." The young Chevreul was admitted to the laboratory of the, at that time, great Vauquelin, who had risen from the position of an errand-boy in a Rouen apothecary's shop to the Professorship of Chemistry in the Institut National and in the Faculté de Médecine, having been a pupil of Lavoisier. With Vauquelin Chevreul remained for twenty years. His earliest chemical work was the investigation of fossils; and it should be remembered that at that time geology was scarcely a formulated science. About 1805 some fossils were unearthed by engineers working in the valley of the Loire, and the young student went there to study them. The result was a small book the next year giving an account of what he found. Finding in those fossil remains the same elements that compose living bodies of to-day, he was induced to examine the chemical composition of animal bodies, and the next twelve years of his life were devoted to that task, most attention being paid to the animal fats, oils, wax and butter. He endeavored to ascertain by analysis the proportions of the various elementary substances, carbon, nitrogen, and hydrogen, contained in these bodies. The chemist of to-day would not think that a difficult task; but at that day there were but few of the apparatus now found in every laboratory, and modern methods of analysis were unknown. This work gave a new book to science, and added such names as margarine, stearin, oleic acid, and butyric acid. For that book the French Society for the Encouragement of National Industry awarded Chevreul a prize of \$600. He was then appointed Professor of Chemistry at the Gobelins Works, and soon after this he filled the chair at the Lycée Charlemagne; and in 1826 he succeeded his great master Vauquelin.

It is a pleasure, even at this distance, to add any tribute of respect to one who rocked the cradle of chemistry; who has since done so much for this cornerstone of medicine. Centenarians are just rare enough to be somewhat as curiosities to unthinking people; but what must be the feeling of respect for one who has continually added to science since 1805; who was living when his countryman Bichat gave

general anatomy to medicine; who had been a laborer in the field of science when Magendie was at work; who was a contemporary of Fourcroy and Vauquelin, of Gall, Rolando, Jacob, Soemering, and Chossat, Chladni and Retzius, Remak and Schwann; of Hamburger, Siebold, Berzelius, Eberle, Valentin, and Claude Bernard, and other physiologists and chemists. It is granted to but few men to see a great science arise, watch it for almost a century, and to be one of its able exponents during that time.

The people in the old country have a very pleasing way of remembering and honoring their silent workers in science; perhaps it will be a custom in this country when our people can spare the time from the ceaseless rush after the dollar.

SOCIETY PROCEEDINGS.

GYNÆCOLOGICAL SOCIETY OF CHICAGO.

Regular Meeting, Friday, June 18, 1886.

THE PRESIDENT, DANIEL T. NELSON, M.D., IN THE CHAIR.

DR. W. W. JAGGARD exhibited

A GRAVID UTERUS WITH ADNEXA, CORRESPONDING TO THE SIXTH MONTH.

The material was placed at his disposal through the courtesy of Dr. H. H. Frothingham, one of the resident obstetricians of Cook County Hospital.

The patient, 30 years old, multipara, came under observation May 17, 1886. While sitting on a chair in the ward, she began to show signs of asphyxia. She was immediately put to bed, but died within five minutes of the beginning of the attack.

Autopsy made forty-eight hours after death.

External appearances.—Some venous hypostasis over dependent portions.

Lungs.—Engorged with blood in lower lobes. Oedematous throughout.

Heart.—Left ventricle partially, but not fully contracted, contained fluid blood, and small clot. Left auricle contained small amount of clotted blood. Right side of heart contained clotted blood in considerable quantity; clots all dark in color.

Valves.—Normal in thickness and competent. Endocardium.—Deep wine-color; smooth.

Myocardium.—Soft, friable. Few spots of emphysema under visceral layer of the pericardium. Left coronary artery contained a clot at distal side of first branch. Intima of artery stained deep wine-color.

Abdomen.—Peritoneum apparently normal. Gravid uterus with fundus extending to the level of the umbilicus. Large corpus luteum in left ovary. Upon opening the uterus a male foetus, in the embryonal position, was found. Placenta separated from the uterus by its own weight and without any effort to detach it.

Intestines apparently normal.

Liver enlarged, friable, deeply congested. Spleen slightly enlarged, and very friable. Kidneys congested; acute pyelitis in each pelvis. Bladder normal.

Brain.—Some congestion of envelopes, and at posterior margin of *tentorium cerebelli* two small, round, firm tumors intimately attached to the *dura mater* and pressing upon cerebellum at posterior internal angle of each hemisphere. Tumors are each about the size of a filbert, upon section presenting a grayish firm surface at periphery, and a disintegrated portion at the centre. Cerebellum.—Soft, and pale throughout, *arbor vitæ* appearance almost entirely disappeared. No trace of hæmorrhage or embolism discovered. Ventricles of cerebrum contained little fluid. The *intima* of the vertebral and basilar arteries presented the same appearance as that of the coronary.

Dr. Jaggard desired to call attention to the condition of the cervix. The cervix is a funnel-shaped object, the neck of which measures 4 cm. in length; thickness of wall, 2 cm. The upper, expanded portion measures 1.5 cm. in length; thickness of the wall 1.5 cm. The mucous membrane lining this funnel-shaped cervical canal differs in its macroscopic characters from the mucous membrane lining the uterine cavity. The cavity of the cervix is filled with a white, coagulated secretion. The insertion of the membranes forms a circle around the upper expanded portion of the cervix, about 7 cm. in diameter, corresponding to the site of several large veins in the muscular substance of the uterus, and the insertion of the peritoneum externally. At this point, the muscular substance of the uterine wall becomes thinner. The average thickness of the muscular wall of the uterus is 1 cm.; that of the cervix 1.5 to 2 cm. Total length of the uterus, 17 cm.

The macroscopical characters of the preparation seemed to sustain the position assumed by Bandl, Küstner and Carl Braun, recently opposed with considerable force by M. Hofmeier. Dr. John Bartlett, a distinguished Fellow of the Society, read a paper entitled *The Cervix Uteri Before, During and After Labor*,¹ July 14, 1873, before the Chicago Medical Society (several years prior to the appearance of Bandl's classical monograph upon the same subject) from which the following extract is made:

"Early in pregnancy the neck of the uterus is called upon to supply its quota to the enlarging body. Speaking somewhat figuratively, as ring after ring of tissue is demanded from the upper part of the cervix, the preparatory development in the remaining portion is such that the length of the neck is not apparently impaired, so that what remains of it as late as two weeks before labor has been mistaken for the entire infra- and supra-vaginal cervix, whilst the loss by the continual transfer from the upper portions of the neck to the uterine walls has entirely escaped notice. That circle of the neck which corresponds at the time of an examination to the limits of its expansion, is regarded by writers as the os internum. The os internum is, of course, as before labor, above the attachment of the vagina, and, near

¹ The Chicago Medical Journal, October, 1873.

term, far removed from the examining finger. The apparent constriction taken for it is simply that point in the cervical walls marking the constantly decreasing line of demarcation between the expanded and yet unexpanded portions of the neck."

DR. A. REEVES JACKSON, in beginning the discussion on Dr. Parkes's paper on the treatment of uterine fibroids by ergot, said: I was very much pleased to hear the reading of Dr. Parkes's paper. I commenced using ergot in the treatment of fibroids in June, 1873. I had used it in eight cases at the time Dr. Byford read his paper based on 103 observations gathered from various persons in this country. I was extremely pleased with the result; two of the patients seemed to be practically cured—that is to say, while there could be distinguished some remaining enlargement of the uterus, the symptoms that were referable to the presence of the tumor were entirely removed, and the patients suffered no inconvenience from the bulk of the uterus. In nearly every case there was improvement. I continued to use it for several years, but have not used it lately—I do not know why. The cases that have been published by those who use it extensively have all shown favorable results except those of Martin, of Berlin, and perhaps two or three others. There seems to be no reason to doubt that ergot, whether given hypodermically, by the mouth, or rectum, does have some controlling influence on the development of uterine myomata, checking the growth or lessening the size of the tumor. Indeed, there is reason to believe that it is one of the very best means of dealing with these tumors. I have used the remedy in perhaps thirty cases. I do not know just what the ratio of success was. In about three-fourths of these cases there was benefit. Sometimes the good effect did not consist in diminution of the size of the neoplasm, but from improvement in the general health of the patient. I was very glad to hear of the almost phenomenal success that followed the practice of Dr. Parkes. In some of the cases he relates the patients were, however, evidently in great jeopardy from the sloughing of the mass, and the difficulty of getting it away before septicæmic symptoms came on. There is great danger, unquestionably, in having a sloughing fibroid retained within the uterus. The treatment by ergot should be accompanied by dilatation of the cervix, so that the mass, when separated from the wall of the uterus, may escape readily. This would lessen that danger. In some cases death has occurred very soon after the stinking discharge appears. Nevertheless, the treatment by ergot is very much less dangerous than any of our surgical methods of dealing with uterine fibroids.

THE PRESIDENT: Have you kept records of any of your cases?

DR. JACKSON: Yes, and I shall be glad, if the interest continues, to report them in detail. I kept accurate notes of the first cases so far as I had charge of the patients. Some of them occurred in the Woman's Hospital, and the patients would go away, and we did not always have means of ascertaining the final results. But of others, occurring in private practice, I can give accurate details.

DR. H. T. BYFORD: I made the assertion that there was no danger of a sloughing of the tumor when it is not situated so that it can be expelled by way of the vagina. This was based on the fact that, unless submucous, it cannot be firmly enough compressed. I have reported a case of fibroid tumor of the vagina,¹ whose thick pedicle was gradually cut through by daily tightening a fine wire about it; when the wire had cut through the pedicle, it was found to have reattached itself, and retained its vitality, showing that tumors of this nature require very little nourishment to keep them from undergoing sloughing. The cases on record are very few in which subperitoneal growths have sloughed from the use of ergot.

DR. W. W. JAGGARD said, with reference to priority in the use of ergot in the treatment of uterine fibroids, that Hildebrandt, of Königsberg, had published a paper in 1872, in which he recommended the drug. The growth of the neoplasm was limited by diminished access of blood, and, in some cases, it was actually expelled from the uterine cavity. Hildebrandt's recommendation was the revival of an old practice. Dr. Wm. H. Byford's paper—Address on Obstetrics—was read in Philadelphia in 1875. During the interval of three years, several papers were written extolling the action of ergot in the treatment of uterine fibroids, both in the diminution of the quantity of blood flowing to the tumor, and also in actively causing its expulsion from the uterus.

DR. HENRY T. BYFORD said: Dr. Jaggard fails to take into consideration the different ways in which ergot acts. It acts first, in a radical way by expelling the tumor, as in the submucous variety; second, in a gradual way by causing atrophy and absorption, as in the interstitial variety; third, in a partial way, by arresting the tumor's growth and activity, as in the subserous ones; fourth, in a palliative way by relieving the symptoms, as in cases of large tumors, near the menopause. Schroeder, in the last edition of his *Krankheiten Weiblichen der Geschlechtsorgane*, gives Dr. Wm. H. Byford credit for suggesting the use of ergot for the expulsion of the tumor. There is no longer any reason to doubt that ergot is the surest and safest cure for all but the very exceptional cases of uterine fibro-myomata. A tolerance of moderate doses is quickly established both by the organs through which it is absorbed and by the general system. Sloughing is almost never produced except in the submucous variety, when it need not be dangerous. For several years past, with one or two exceptions, I have not given ergot in any other way than by the rectum. I use 5 to 8 grains of Squibb's extract of ergot twice a day and continue it for two or three years, with favorable results. I remember one case in which the tumor extended almost to the umbilicus when I first saw her, five years ago. It was an irregular, nodulated tumor, mostly subperitoneal, with projections larger than the fist, filling up the pelvis, and to a great extent the false pelvis also, and sometimes caused excruciating pain by its pressure. The patient had repeatedly bled through six and eight weeks, and must have lost 100 pounds. Tampons were required to save her life. I never saw paler mucous membranes in a living

¹Chicago Medical Journal and Examiner, August, 1885.

being. It was a very much worse case than many which I continually find cited in medical literature, in which hysterectomy is considered necessary. The patient begged to have the tumor removed. She could not take the ergot for any length of time either by rectum or mouth; but after a while she tolerated 5-grain rectal suppositories, and has passed the menopause. The tumor, having lost its activity, has become considerably smaller; while she, having regained her hundred pounds, has become considerably larger. I have a case which had been treated for a year with all of the most approved remedies, except ergot. When I first saw the patient, two years ago, she weighed eighty-three pounds; she had a nervous chill and almost fainted when I first entered the room, because I was a stranger. She had not slept for weeks except under the influence of narcotics, and had symptoms of acute tuberculosis. She was in the habit of bleeding steadily from three to six weeks, and was being so rapidly destroyed by the loss of blood that I at first had to use the tampon. She was put upon 8 grains of Squibb's fluid extract of ergot per rectum and tincture of iron by the mouth. Her health improved rapidly and the hæmorrhages progressively diminished. Her lungs were recently examined by Dr. H. A. Johnson, who found the remains of old trouble, but no tendency to unfavorable changes. Her cough, which had lasted so long, has entirely left her. She now takes the ergot a part of the time only. Her menses last four days, are natural in quantity and quality, and are followed every two or three months by a watery discharge of a faint pinkish tinge. She cannot feel the tumor now, although a projection the size of a child's head was formerly felt by her between the umbilicus and left groin. It might be said of this case that it was also a very proper one for operation, and one in which ergot, if harmful to the system, would have done injury. I have similarly relieved other cases nearly as bad, and cannot help believing that, when treated early, judiciously and persistently by ergot, fibroid tumors of the uterus will show a mortality of 1 or 2 per centum instead of 10 per centum as at present; that hysterectomy for fibroids, with its mortality of 20 to 40 per centum, will eventually become an interesting relic, and the removal of the appendages a precious rarity.

DR. E. W. SAWYER said: There is one point that was not alluded to by the reader of the essay, and that has not been spoken of in the discussion. The fact that the point has been proved in practice shows that it is worthy of attention. That ergot will cause atrophy of a uterine fibroid, causing a detachment by ulceration and expulsion, is a well-established fact. When the fibroid is submucous, or nearer to the mucosa of the uterus than to its peritoneal surface, I have no doubt that that process can be continued and completed with safety. But let us suppose a tumor very close to the peritoneal surface; this process of atrophy takes place, the peritoneum ulcerates through, and the life of the woman is jeopardized. Such a condition occurred in a patient seen by the President of this Society, and it was shown that had the patient lived long enough the fibroid might have

been thrown off through the abdominal parietes. This patient died of peritonitis. The large and partially detached fibroid was in a sac containing a great quantity of pus. This sac had ruptured, occasioning the peritonitis.

DR. F. E. WAXHAM said: I would simply add my testimony as to the value of ergot in the treatment of submucous fibroids, by citing a case: A woman 45 years old came to me some time ago complaining of copious hæmorrhages at her menstrual periods, and upon careful examination an enlarged uterus was found, which nearly reached the umbilicus. The diagnosis of fibroid of the uterus was made. This woman was placed upon ergot, combined with opium, to control the pain, which she took for several weeks. Between the second and third months after commencing to take the ergot, I was called to her in great haste and found her apparently in labor, the uterine contractions quite regular and very severe; a partially dilated os and the tumor presenting. This tumor was expelled after two or three hours. It was nearly as large as a child's head at time of birth. The patient made a complete recovery.

THE PRESIDENT: In what state was the tumor?

DR. WAXHAM: I can hardly say it was softened, but it was fleshy in character, and some pus upon it as though it had suppurated. It was somewhat offensive, I remember. I attended her for some weeks subsequently; there was some febrile reaction, but no serious trouble followed.

THE PRESIDENT said: I have reported a case in which a tumor was thrown off without sepsis. I have had since quite a series of cases in which tumors have been thrown off; some have been absorbed and there has been a various history, which I hope to make the subject of a special paper, and would like the assistance of others in making up a history of these cases. I think we are specially favored in having with us Dr. Wm. H. Byford, who has had such extended experience in these cases.

DR. WM. H. BYFORD, in closing the discussion, said: Mr. President, you are right in supposing that I feel great interest in this subject. I have made it a study for a long time. Perhaps as good a way as any to introduce my views on this subject to the Society, will be to go back to the commencement of my own researches in this matter. In 1872, as Dr. Jaggard has said, Hildebrandt commenced a series of experiments for checking the hæmorrhages connected with fibroid tumors of the uterus, by giving hypodermic injections of the extract of ergot, and succeeded in a great many instances in suppressing the hæmorrhage and relieving the patient from the inconvenient symptoms. During these experiments he also ascertained that the tumor would sometimes disappear. I think his statistics were not large, and that he only reported a very few, perhaps three or four, cases in which the tumors disappeared by atrophy during the time he treated them in this way. In 1874 I was elected to the chairmanship of the Section of Obstetrics in the American Medical Association, and as these experiments of Hildebrandt had attracted considerable attention, I thought it would be a good time to make some investigations as to the

value of his facts. I commenced correspondence over a large portion of the United States and Europe, but especially communicated with my friends in this part of the country, among whom were my immediate associates in this city, who had been engaged in using hypodermic injections of ergotine according to the method of Hildebrandt, once in two or three days. All of them bore testimony as to the efficacy of that kind of treatment, and as to the fact that these tumors could be made to disappear in a great many instances by atrophy, and in a great many more the symptoms could be relieved so that the patient was rendered comfortable, the presence of the tumor giving them but little inconvenience. Some of the gentlemen with whom I had correspondence had been using the ergot in different ways, giving it by mouth, giving it per rectum, and injecting it into the tumor itself, and by various other methods. I noticed one fact in my own practice and that of my friends, which was that the more frequently the ergot was given the more powerful its action was. In giving it two or three times a week hypodermically by the Hildebrandt method, there is very little distress produced by it; but the tumor may gradually disappear and the symptoms get better. I collected 103 cases from different parts of the country, and in all of them the attention of the practitioner was directed to the point of causing the disappearance of the tumor by atrophy. During the time I was making these investigations cases of fibroid tumors occurred in the practice of my friends, who consulted me. One was a remarkable instance in the practice of Dr. Merriam. I remember the particulars. The patient was a little Irish woman who had a tumor almost large enough to reach to the umbilicus. He commenced the use of ergot in September, 1874, twenty drops of Squibb's fluid extract three times a day. It produced so much contraction of the uterus and so much pain as to alarm the patient and the doctor himself; he thought these pains ought to be suppressed, and as a consequence he would intermit the use of ergot, give anodynes to stop the pain and get relief from the sufferings of the patient, but would recur to ergot as soon as his fears had subsided. In January, 1875, he directed her to recommence the ergot and increase the amount. He gave her, I remember very well, twenty-five drops of Squibb's fluid extract three times a day. In March, which was about two months from the time he began giving her ergot in that way, the patient commenced having expulsive pains very much like labor, and not long after that, probably about March 20th, there commenced to issue from the vagina a putrid liquid that was very offensive and which contained small pieces of organized substance. He became alarmed and entirely withdrew the ergot, supposing he was doing mischief, but the death of the tumor had been produced and as a consequence the uterus continued its action to throw off this foreign body, until April 5, 1875, he was summoned in great haste to see his patient. I was also summoned. Upon arriving at the house, which he did before me, he found the tumor expelled, part of it laid in the vagina and part between the limbs of the patient, a protruding mass

almost the size of a child's head. It was not expelled in a lump, but was broken in pieces that would represent that size. The patient at that time had septic fever, with increased temperature and increased frequency of pulse, etc. The doctor and I both felt uneasy about her, but she very soon rallied and in a short time was well, and since has given birth to a child.

That was my first observation as to expulsion of tumors of that kind. It started a train of thought in my mind and led me to think about increasing the ergot beyond the amount that had usually been given for producing atrophy. In the same year, July, 1875, I commenced giving it with the view of expelling a tumor. I gave my patient at first fifteen drop doses of Squibb's fluid extract three times a day, and increased it until the patient was taking a teaspoonful of ergot three times a day. On August 15th, about five weeks after I commenced using it, the tumor was broken up and expelled from the vagina. It was expelled by pieces, the first piece about as large as my thumb, of a grayish kind of substance that smelled very badly. The action continued; I was somewhat alarmed and gave the patient anodynes, but the uterus had already commenced to act on the tumor and expelled it, as it would any foreign body. In December of the same year I had an opportunity of repeating the experiment, and the case terminated in the course of six weeks, by the same method of administering the ergot. In 1876, on returning from the world's exposition at Philadelphia, I was requested to call at Coldwater, Mich., to see two patients, one with cancer and one with a tumor. I found one of these patients with a tumor as large as my head, the measurement of the cavity being fully six inches. I told her I believed the tumor could be expelled if she was willing to go through the process. I felt uneasy, however, to leave her to use such medicine by herself, and tried to teach her how she should proceed when the expulsion should take place. She took the ergot three months without much effect, except that occasionally she would have a paroxysm of pain; after that, however, the pains became so very severe that she could not take the ergot much of the time. But, brave and intelligent as she was, she repeatedly resumed it, and finally the tumor commenced to come away. It came away in about five weeks from the time the first symptoms of expulsion occurred. She wrote me a description of the method of expulsion. She said at first small lumps made their appearance and passed out of the vagina; after the second day they became larger, and on the third and fourth days they seemed large enough to fill up the vagina. With her scissors she cut off pieces of it and pulled at it to assist its removal. She labored at it two or three days until it was all expelled. In about three weeks thereafter she came to see me, and the uterus had shrunk back to near its natural size. She has since had the menopause, and is now in good health. She sent me at that time a quart cup full of this expelled fibrous substance.

Another case occurred in the western part of this State, under the care of Dr. Crandall, of Sterling.

The patient came, by his directions, to see me, and I found a tumor of considerable dimensions and advised her to take ergot. She went home and in about fifteen or twenty days got her work done up, as she expressed it, took three doses of thirty drops of Squibb's fluid extract of ergot, and started up such a process of expulsion that, notwithstanding the efforts of her physician to stop it, the pains went on to the expulsion of the tumor, which was completed in about three weeks.

Dr. Wm. Fox, of Milwaukee, three years ago sent me a report of another similar case. In summing up these observations, I have known personally of twenty-six cases of expulsion of the tumor in this way. With reference to the dangers connected with the expulsion, I would say that only one out of these twenty-six cases proved fatal. They all had septicæmia to some extent, but as soon as the mass of dead tumor was removed the patient commenced to recover and got well. Some of the patients had no assistance. This one patient in whom it proved fatal lived in Monmouth. It occurred about six years ago. She was a lady who, like other foolish women, distrusted her home physicians, and she came here, supposing she would find better treatment. I advised her to take ergot, and in about three months the pains commenced that caused the tumor to be expelled. She came here with the lower part of the tumor hanging from the vagina and uterus while the upper portion was clinging to the cavity in which the whole of it had been lodged. She was then laboring under a high fever. The smell was terrible. She came to the Tremont House and it was several hours before I could see her. When I arrived it was a very simple matter to enucleate it, and I removed it in a few minutes. But she had already received a fatal poisoning from the retention of the dead tumor. This is the only case I have known to prove fatal. I do not get a history from other gentlemen of any more unfavorable results. They all tell me they are frightened at the symptoms, and they are afraid the patients are going to die, but they do not die. When the mass is taken away and the vagina washed out the symptoms disappear. Since thinking of this matter and observing the effects of this remedy I have thought I could come to definite conclusions as to the conditions under which we might predict the expulsive effects of ergot by the appearance of the tumor. You know that it is not a very common thing to find a case in which there is a single tumor in the fibrous tissue of the uterus. More frequently these tumors are complex. Quite a number of nuclei of formation; we often see in one uterus four or five, sometimes fifty different points of solidification. Now a single, or even a double tumor, located within the circle of the fibrous arch of the uterus near the mucous membrane, is the kind that I think may almost certainly be expelled. If you find a case of symmetrical development, where the uterus seems near its normal shape, no matter how big, so it is normal in shape, oval, or globular, without any large projections standing out in various directions, feeling somewhat elastic to the touch, and attended with hæmorrhage, you may be pretty sure you can expel

the tumor by commencing with small doses of ergot and increasing them in size, and then when the pains begin, not to stop them. The presence of severe pains frightens a great many men from finishing what they have begun. If I were to try to explain this operation I would say when ergot is given in this way, after a while the tumor becomes starved, the supply is cut off so there is not blood enough to support it, and very soon it dies in consequence of this strangling process. When it dies there is, at the same time, gangrene of the mucous membrane covering it; then it becomes a foreign body and you cannot keep the uterus from expelling it. The expulsion is a consequence of this starvation and killing process in the tumor. As to the action of ergot in tumors that are not submucous, of course I know that tumors not submucous cannot be expelled. There is what is called the interstitial tumor, developed in the central stratum of the fibrous walls of the uterus; these are the proper subjects of the Hildebrandt process for atrophization. Then with reference to the effect of ergot upon subperitoneal tumors: I have often been asked the question, Can ergot affect these subperitoneal tumors? I think they are frequently starved out and cured; when not too near the peritoneum there is no danger of their becoming detached and putrid in the peritoneal cavity, because the action is from the tumor. In the submucous tumor the contractions are all towards it and none from it. There is one circumstance to be taken in connection with these tumors and the action of ergot upon them, that has not been sufficiently considered. A large proportion of them growing to any considerable size contract attachments to the peritoneal membrane, the intestines, omentum, or the walls of the abdomen, and in making this attachment they get a new supply of blood, which makes the life of the tumor more tenacious than it would be otherwise. This very process of adhesion to the walls of the abdomen is, more than any other, the cause of their great size and the change from a fibrous to a fibro-cystic tumor. We need not expect such tumors to be affected by ergot. There are a good many other things that interfere with the successful use of ergot, of which I cannot now speak. I am grateful to my western associates who have assisted me by facts and experiments on this subject. If you go to the eastern part of the United States they will tell you that ergot is of no use in the treatment of fibrous tumors, or it is too dangerous; the patient cannot live under the pains of expulsion, etc.; but if these same gentlemen had a patient in labor they would urge the pains instead of stopping them. Most physicians who do not believe in the efficacy of ergot use Hildebrandt's method pretty much altogether, which produces tonic contraction of the fibres of the uterus, but does not go to the extent of causing expulsive pains. Then, again, there is too great apprehension on the part of the profession generally of the dangerous poison of ergot. I do not know whether the history we have of the poisonous influence of ergot in producing nervous diseases, gangrene, and so on, is true; whether the observations that led to that teaching were correct at one time or not, but

I know that after the use of ergot persistently for two or three years in the same case, I have never seen any evil influence produced by it, unless it is in cases where the violent action of the uterus would be regarded as such. I have purposely avoided saying anything about the *modus operandi* of ergot in causing contractions in the uterine fibres, because that is now sufficiently understood by the profession. But, Mr. President, I feel that I have occupied too much of the valuable time of the Society already, and will say no more.

DR. WM. H. BYFORD presented

A STUDY OF THE CAUSE AND TREATMENT OF PELVIC HÆMATOCELES.

The author cited the case of a non-suppurating, retro-uterine hæmatocele of six months' standing, which he evacuated *per vaginam* March 18, 1886, and then treated with antiseptic irrigations. She was up and about the house in eleven days. As the odor and discharge were still causing discomfort, the doctor, influenced by the advice of Apostoli and Doléris, curetted the cavity. He found no more blood or debris, but started up a mild attack of local peritonitis, which delayed instead of hastening the cure. The patient left the hospital in a little less than a month after the cessation of all discharge. A small lump of induration extending from the abscess opening to the right sacro-uterine ligament was all that was left of the tumor.

The following résumé of interesting points in the case is given:

1. The length of time from the occurrence of the hæmatocele to the time of operation, about six months.
2. The method of opening the cavity, viz.: by first tearing the vaginal wall, and afterwards the sac wall.
3. The absence of fluid in the tumor.
4. The breaking up of the mass with the finger without an attempt at thorough curetting or removal of the entire contents.
5. The complete disintegration and discharge of all bloody substance in thirteen days.
6. The absence of high temperature—102° F. having never been reached.
7. The small amount of anodyne required—one dose (except the two doses to relieve the irritation from subsequent unnecessary curetting).
8. The toleration of strong antiseptic solutions. It was necessary to weaken them on account of their effect upon the vagina.
9. The absence of the usual amount of odor in such decomposing masses.
10. The large quantity of food taken throughout.
11. The absence of any kind of sickness from the beginning until the cavity was curetted.
12. The curetting of the cavity on the thirteenth day delayed her recovery, producing the only serious symptoms that were noticed.
13. Notwithstanding a setback of ten days caused by the curetting, she was well enough to go home inside of a month and dispense with treatment.
14. The attack came on after a miscarriage.

P. F. Mundé reports two new cases of hæmatoma successfully operated upon three and six weeks, respectively, after their occurrence, both large, and resulting from or after abortions. (*N. Y. Medicinische Presse*, Vol. 1, No. 1, Dec., 1885.)

Five other cases are briefly related, four extra-peritoneal hæmatomas and one large retro-uterine hæmatocele, which had come under the writer's observation during the past two years, and which were successfully treated on the expectant plan. He was unable to find justification in any text-book for having operated in the absence of any threatening symptoms until he procured the last edition of Billroth & Lücke's "*Frauenkrankheiten*" and Schroeder's text-book (both of 1886). He cautions against taking the advice of Bandl, to operate after the first subsequent menstrual period, or that of Apostoli and Doléris, to operate immediately by the galvano-puncture wherever and whenever found. Operations at such times are connected with what are designated as immediate dangers, viz.: "a recurrence of shock, hæmorrhage, or (if hæmostatic tampons be used) of inflammation; or of septicæmia followed by inflammation, if antiseptic injections of sufficient strength be used."

The dangers of the expectant treatment are mostly remote, and are such as "suppuration, septicæmia, perforation, and prolonged pressure upon, and displacement of, surrounding organs, with their results, viz.: the aggravation and perpetuation of pre-existing pelvic disease, or the originating of new ones."

While recognizing the necessity for evacuation within the first three or four weeks in certain exceptional cases, he would, as a rule, delay operating long enough to avoid the immediate dangers, yet not long enough to incur the remote dangers of delay. The patient must invariably be kept in bed and the tumor should be left alone until the primary acute symptoms subside. If the tumor remain hard and diminish in size no matter how slowly, it should be left alone as long as the symptoms do not become worse. If the tumor remain stationary and boggy to the feel, and the symptoms begin, after a few weeks, to increase in severity, it must be operated upon; or if the symptoms remain without improvement, while the tumor shows no signs of being absorbed, it is better not to wait for serious symptoms, but operate in the subacute stage, or when the symptoms have subsided as much as they will. There is a certain class of cases, like the first one reported, in which the acute symptoms subside, the patient recovers considerable strength, but the tumor remains elastic, or boggy, and almost stationary, and interferes with her usefulness. If the patient cannot, from adverse circumstances, or does not wish to make an invalid of herself for the many months of quiet and carefulness requisite for safe absorption of the organized clot, she should have the benefit of an operation at a time when it is almost devoid of danger.

Dr. Byford would not select the method of operating recommended by Apostoli and Doléris because two sittings would be required for a complete operation, and because the use of the curette through so small an opening as would be justifiable by galvano-puncture is not devoid of danger. He prefers punc-

turing and tearing with a dilator, first the vaginal and then the cyst wall, to Zweifel's method of incising, on account of the less liability to trouble from hæmorrhage. He also advises the attack of such retro-uterine hæmatocèles as are accompanied by obliteration of the Douglas cul-de-sac by puncture and dilatation per rectum, when possible. The difficulty would be but little greater than the dilatation of the fistulous opening of a pelvic abscess.

Thorough curetting is condemned as dangerous, but a breaking up of all solid material by the finger, and the trusting to copious, strong antiseptic irrigations (which can be endured much stronger if the abscess walls are not scraped), is recommended. Hydrarg bin-iodide $\frac{1}{100}$, or bi-chloride $\frac{1}{100}$, or acid carbol. $1\frac{1}{2}$ to 2 per cent. twice or three times a day, as necessary. Instead of a drainage-tube being used, the finger may be passed through the opening daily in order to dilate and insure free discharge. On account of diagnostic difficulties an aspirating needle should precede the use of the knife.

The discussion of Dr. Byford's paper was deferred until the next regular meeting.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, April 28, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

DR. JOHN B. HAMILTON showed some

GRANULES OF BONE REMOVED FROM A TUMOR.

The history of the case is as follows:

The patient, a girl of 19, had had caries of the spine in her youth and was at present a hump-back in consequence. About two years ago an abscess formed anterior to the left trochanter in the left thigh. This had been aspirated and about one quart of pus drawn away. About one month ago a "hump" appeared just back of the left trochanter. When the doctor first saw her he supposed that it was the reforming of the abscess. The tumor, however, was hard, and on palpation there was crepitation such as one gets in emphysema of tissues. He cut down on the tumor and removed the exhibit, which was contained in the fibres of the tensor vaginæ femoris muscle. One would suppose that such a hard mass would have produced suppuration, but in this case there was no pus or inflammation, and the pain which had been present since the first appearance of the tumor must have been due to pressure on the sciatic nerve. His theory of the presence of the deposit was that during the process of caries going on in spine in her youth, particles of exfoliated bone had gravitated with the pus which had formed the abscess and had remained on its removal.

DR. BERMANN exhibited a portion of

A LARGE NASAL POLYPUS

which he had removed. When the patient presented himself to him the polypus, which had been growing eight years, was visible protruding from the left nostril and also in the posterior nares, completely oc-

cluding that side of the nose. He had been obliged to remove it with the cautery, in sections. The exhibit was about half of the polypus, the remainder not yet having been removed. He had found that the inferior turbinated bone on that side had been eroded, and that there was a large cavity there.

DR. LYON showed the photographs and detailed the history of a case of

CANCER OF THE LEFT MAMMA,

occurring in a patient in the Government Hospital for the Insane. In 1865 the woman became afflicted with a suicidal melancholia, probably brought on by puerperal convulsions. She was at that time extremely violent, but has gradually become less so, especially since 1883. In that year a tumor was discovered just above the left breast but apparently not involving the gland. In June, 1884, this tumor, which was as large as a small egg, was removed, and a microscopic examination proved it to be an alveolar sarcoma.

The wound healed well. Two months later three distinct tumors had each reached about the same size as the first one. One of these was in the left axilla and the two others were near the ends of the cicatrix of the first one. These were removed, and Drs. Blackburn, pathologist to the hospital, and Formad, of Philadelphia, pronounced them soft carcinoma. A third and fourth operation were done during the next six months. Each time the growth was larger, more rapid, and involved more tissue, and each time the incisions healed almost by first intention.

The tumor reappearing a fifth time, Dr. J. Ford Thompson was called in consultation and advised that no further operations be done. In the ten months which have passed since the last removal the tumor, as shown in the photographs, has become eleven inches long, seven inches wide, and projects a mass of suppurating and floridly granulating tissues two inches high and weighing probably several pounds. It extends from the shoulder downwards throughout the entire breast, with a continuation to the left as far as the floating ribs in the axillary line. There is wasting, and though there is no external evidence of involvement of any internal organ, it is probable that such is the case.

What he wanted especially to call attention to was the effect the cancer had as a counter-irritant on the partial dementia of the patient. He said that the element of pain is, in some insane persons, much less prominent than in sane persons. This we see in some instances of self-inflicted injuries which seem to have a quieting effect. In this case pain has never been much complained of, though it is possible that it never has been present in any great degree. Here the only other treatment besides supportive has been 15 drops each of tinct. opii and belladonna three times a day. This has been sufficient to keep her in a quiet and perfectly manageable frame of mind. When omitted, however, there is some little complaint of pain. The terrible odor emitted from cancer has been treated, with more or less success, with hydro-naphthol. The cancer is now rapidly breaking down.

DR. H. D. FRY presented the

BRAIN FROM A CASE OF TUBERCULAR MENINGITIS.

The history of the case is as follows: Dr. Fry saw the case first on April 18, 1886. The patient was a white female child 17 months old. There was a good family and personal history, except that child was a little late in dentition. For three or four weeks previous to his first visit his patient had been restless and fretful, there had been a desire to rest its head against its mother's shoulder and right-sided hemiplegia, as shown by the child constantly carrying its hand to that side of the head. There had been only occasional vomiting and no constipation—rather the contrary. When first seen the pulse was 100, temp. only slightly elevated. The mind was dull, the pupils dilated, and there was complete left hemiplegia. The child gradually became less susceptible to external impressions, and on April 21 it could not be aroused. The temperature had several times reached 103°. At this time the pulse was 160, the pupils widely dilated, though reacting to light, and there was alternating internal squint. The right eye was staring with the lids wide open while those of the left eye were bolted. There was difficulty in swallowing. The muscles of the right upper extremity and shoulder were affected with clonic spasm and the fingers of the right hand were flexed on palm. Aggravated attacks of spasmodic contractions of the muscles were accompanied by hurried and panting respiration. Occasionally the contractions involved the left upper extremity, but at such times were of short duration. The child lived two days longer, the convulsions meantime ceasing and the coma deepening.

Dr. Fry said that complete hemiplegia is uncommon in tubercular meningitis. The authorities (Meigs and Pepper and Flint) mention incomplete paralysis as of occasional occurrence, while J. S. Smith and Henschel make no mention of this condition. The latter author, however, gives this as a symptom of "tuberculosis of the brain." The diarrhoea present in this case he thought was due to tuberculosis of the intestinal tract.

The brain was examined by Dr. Lamb, of the Army Medical Museum, and presented but little of a pathological appearance. There was some dilatation of the ventricles, most marked on right side. Pia mater much congested, and in vicinity of right middle cerebral artery showed many minute opaque spots, which have disappeared since placing the specimen in alcohol. None found elsewhere. To the naked eye there appeared to be tubercles. Fluid in ventricles and general cavity increased in quantity and was turbid; substance of brain congested.

DR. TAYLOR said that he had had a case of a child 20 months old who had had symptoms very much as the above. There was bolting of eyes and fixed stare. The child could swallow when liquid food was put in its mouth. His patient had remained comatose for seven or eight days and then slowly began to recover and was now convalescent. He had diagnosed tubercular meningitis, but was beginning to doubt its correctness. He had at present another case of spinal meningitis the etiology of which might

be either idiopathic or traumatic. In this case there had been opisthotonos. This was also getting well.

DR. SMITH asked if any gentleman had had any experience with opium in meningitis. In his hands the bromides and the ordinary method of treatment had been of little avail, and he had not only had but few recoveries from any of the forms of meningitis, but had heard of but few. He intended using opium in some form in his next case.

DR. TAYLOR said that he had used tr. opii with good result in one of the cases just reported.

DR. HAMILTON remarked that he was surprised to hear Dr. Smith say that he had heard of but few recoveries from meningitis. The books were full of reports of recoveries. In the winter of 1873 and 1874 he had seen in his own and others' practice about forty cases of epidemic cerebro-spinal meningitis, and of these 50 per cent. recovered. The cases were not, of course, all of the same severity, but the diagnosis in each case was plain. They would begin with dilated pupils, opisthotonos, etc., and in many cases were followed by remarkable sequelæ, such as abscesses in back and in neck, enlarged glands, etc. Some of the patients would be dead in several hours from the beginning of the attack. At the first of the epidemic the treatment had been the usual one, bromide of potash, iodide of potash, calomel, etc. But on looking up the literature of the subject in an old book published in 1811, he had found recommended hot baths, non-stimulating forms of the diuretics, ergot and aromatic spirits of ammonia. This plan was at once adopted and many cases recovered.

DR. MAGRUDER related the case of a child he had been called to see, who had been ailing and losing flesh for some months. There was a history of phthisis on both its father's and mother's side. There had been constant vomiting and diarrhoea for some time. When first seen it was in convulsions; warm mustard baths, blisters, calomel and bromide of potassium with chloral relieved it from these and they never returned. There was strabismus of one eye, convulsive movements passing over the whole body, and the fingers were contracted on palm. Jactitation was marked, while there was deep coma. This condition lasted for a week, the same treatment being continued. The vomiting stopped. On the eighth day the child began to show some consciousness, but was totally unable to move limbs. In a month the strabismus and contraction of the fingers on the palm were better, but both would increase on excitement. He put her on emulsion of cod-liver oil, and in six months she was able to walk, having had to learn this over. The family then removed from the city, but letters told him that the patient was doing well, but that any excitement brought on violent jactitation. Eighteen months after the sickness the child was operated on to rectify the strabismus, but without much success. The child is at present perfectly healthy in appearance, but her memory is defective, she is very nervous, and the strabismus continues. Has taken cod-liver oil all along. Dr. Magruder thinks that, considering the history of tuberculosis in both parents and the symptoms present in this case,

he is justified in calling this a tubercular meningitis.

In his dispensary practice, also, he has had several cases much benefited by counter-irritants, iodide of potassium and mercurials. The iodide must be given in fairly large doses, gr. x t. i. d. He mentioned a dispensary case which had dilated fontanelle and convergent strabismus. This child was able to walk, but not getting any better he had called in Drs. Burnett and Marmion. The child finally became entirely blind and the head increased in size. The child's mother had annoyed him greatly by begging on the streets and telling people that her child had been made blind at the Dispensary.

DR. SMITH asked Dr. Magruder if he considered a case of meningitis cured when the child was left blind and with a weak mind?

DR. MAGRUDER replied that he did so far as the meningitis, the lesion he was called on to treat, went.

DR. W. W. JOHNSTON said that it would be well to define the kind of meningitis talked about. It is a concomitant of so many states that such a question as Dr. Smith asked first becomes a pertinent one. Simple meningitis gets well. *Cerebro-spinal fever* is not meningitis, but a specific disease, and he believed the cases reported by Dr. Hamilton to be of this kind. The treatment he had used so successfully was addressed to the general symptoms, and in reality meningitis does not always occur in these cases. He had seen cases with symptoms such as Dr. Hamilton mentioned, notably in a family of refugees during the war. Several members died in rapid succession, some in a few hours from the first symptoms. On one or two appeared the purpuric spots which give it the name of *spotted fever*. There may be meningitis in Bright's disease, and tubercular meningitis is merely a symptom of general tuberculosis. When there are tubercles enough in the brain to produce these symptoms the cases die, and tubercle will be found in other organs.

In the case reported by Dr. Magruder of a girl recovered from tubercular meningitis, he does not consider her cured except of one single lesion, for there remains a weak mind and convulsions. The doctor has tried counter-irritants, calomel, iodide and bromide of potash, ice to the head, etc., but where he was sure of his diagnosis of tubercular meningitis the patients never got well. If they did get well it militated against its being tubercular. He said that he had noticed as one of the earliest symptoms that the patient began to stutter. Where a child had previously been talking all right it began to stutter and hesitate or remain silent. This comes before the constipation and other initial symptoms in many cases.

DR. HAMILTON said that he was aware that there was a difference between *cerebro-spinal fever* and *simple and tubercular meningitis*. They must, however, be very much alike, for many of the post-mortem appearances are the same in the two. J. Lewis Smith used synonymously *cerebro-spinal fever*, *spotted fever* and *cerebro-spinal meningitis*. It is also termed epidemic *cerebro-spinal meningitis*. In addition to the sequelæ already mentioned by him paralysis may follow; differing, however, from that which follows scarlet fever.

DR. HARTIGAN asked Dr. Fry if there had been any jaundice in his case? Dr. Fry said there was none. Dr. Hartigan stated that in several cases he had observed this symptom, and he thought that he had been able to trace its source to the fact, which he had verified in several post-mortem examinations, that there was a deposit of tubercles around the bile ducts. As Dr. Johnston stated, tubercular meningitis was merely a symptom or accompaniment of general tuberculosis, which, when it attacked the brain, began at the base about the fissure of Sylvanus. The cerebellum and pons may also be attacked in the form of a yellow mass or tumor. Dr. Hartigan said that his treatment was generally with the liq. hydrarg., bichloridi and general hygiene. Iodide of potassium and iodoform were also recommended for their absorbent effect. There did not seem to be enough disease in the brain exhibited to account for the rapid death, and if the post-mortem examination was extended, this would likely have been confirmed.

DR. W. W. JOHNSTON said that he did not mean to correct Dr. Hamilton's pathology, but he still thought himself right in saying that *cerebro-spinal fever* is not a meningitis.

DR. HAMILTON said that in the beginning he had asked Dr. Smith to what form of meningitis he was alluding when he (Dr. S.) remarked that he knew of but few cases of meningitis which got well. Dr. Smith had replied *all forms*, and he (Dr. H.) had accordingly mentioned the above cases which he believed to have been meningitis. He had not in the course of his remarks alluded to tubercular meningitis.

DR. MAGRUDER said that he had seen iodoform recommended in the London *Lancet*. Here the scalp had been shaved and an iodoform ointment applied. Coryza had followed in a few days, and the ointment was given up.

DR. BOARMAN asked Dr. Fry if his case had scrofula? He had lost several cases with this struma. He had also observed the *tâches meningitiques* in several cases. Dujardin-Beaumetz recites a case of recovery from tubercular meningitis.

DR. BERMANN said he did not believe that an absolute diagnosis of tubercular meningitis could be made without a microscopical examination. He had had his attention called by a physician in London to the bright red and shiny appearance of the tip of the nose as one of the early symptoms of tubercular meningitis.

DR. HARTIGAN said that the disease might be differentiated by ophthalmoscopic examination. If tuberculous, the so-called "cloudy swelling" or "tuberculous inflammation" of the retina might be found.

DR. FRY, in closing the discussion, said that he had hoped some one would have mentioned the hemiplegia which was an interesting occurrence in his case. In reply to Dr. Boarman he would state that his case was not scrofulous. Hanoch mentioned that in acute tuberculous cases where calomel was used the patient might apparently get well, but there would be relapses and finally death. The post-mortem in such cases showed successive crops of tubercles and adhesions. He did not think that Dr. Magruder's case was tuberculous.

Stated Meeting, May 12, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

T. E. MCARDLE, M.D., SECRETARY.

DR. J. FORD THOMPSON presented the

SAC OF AN OVARIAN CYST

recently removed by him at Garfield Hospital. He presented the specimen to the Society on account of the size of the tumor and the condition of the patient. He saw the woman, with Dr. D. R. Hagner, more than two years ago. The tumor was then very large, and had been growing for a number of years. He advised an operation for its removal, but his advice was not heeded. She spent the last two years and a half in her room knitting and doing some light sewing. Some weeks ago Dr. Hagner again requested him to see her in the hope of giving some relief by tapping, as a radical operation was considered out of the question on account of the woman's condition. Dr. Thompson, however, advised an operation for the removal of the tumor, and she was sent to the Garfield Memorial Hospital on the following day. A consultation was held and it was decided to operate as the only chance of saving the patient's life. Dr. Thompson feared complications, and the irregular shape of the tumor gave him some uneasiness, as he was uncertain as to its partial solidity. The operation was performed on the afternoon of May 4, 1886. There were no adhesions or complications of any kind. The tumor, which had appeared on the patient's left side nine years ago, when she was 47 years old, and seven years past the menopause, was found to be a multilocular cyst weighing 40 pounds. The fluid contents weighed $38\frac{3}{4}$ pounds. The contents of the smaller cysts were, as usual, of a thicker consistency than the contents of the large cyst.

He ligatured the pedicle with silk and cut it with the thermo-cautery. The stump was dropped into cavity and three rows of sutures closed the abdominal wound, which was only three inches long. There was no shock, and the pulse and respiration improved immediately upon the removal of the tumor. She slept well all night, and to-day, the eighth after the operation, she says she is feeling splendidly. The sutures were removed this morning. The only complication has been an increase of temperature for several days, which Dr. Thompson considered due to the removal of pressure from the circulation, for there is no symptom of any other local or constitutional disturbance.

DR. J. TABER JOHNSON said he was glad Dr. Thompson had operated successfully upon a patient in such a low condition, for it would serve to encourage other surgeons and patients. It was remarkable that so large a tumor could be removed through so small an incision. We all know, however, that the smaller the incision the greater the safety to the patient; provided, of course, that it be not so small as to be bruised by the removal of the tumor. Three weeks ago he had removed an eight pound tumor through an incision two and a half inches long,

and indeed two inches would have been long enough. The patient has had no trouble other than stitch-hole abscesses and a slight burn from the thermo-cautery. Otherwise she has suffered no pain at all. By severing the pedicle with the thermo-cautery, its raw surface is prevented from becoming attached to the intestines, omentum, or pelvic peritoneum. He related a case in his own practice where the pedicle had become attached to the peritoneum, though other causes accounted for the death of the patient. In some cases of ovarian cyst the fluid is so thick that it is with the greatest difficulty fluctuation can be obtained. On Friday last he opened a woman's abdomen expecting to find a fibro-cystic growth. It proved, however, to be a cyst with walls varying from an inch to four inches in thickness. The fluid weighed only eight pounds, whilst the sac weighed twenty. He was compelled to make an incision more than six inches long. He desired to call attention to one other remarkable point in Dr. Thompson's case, namely, the length of time the woman had suffered; for three years is considered the average number of years a patient will live with such a tumor.

DR. THOMPSON wished to add one remark concerning diagnosis. There was a peculiar sensation rather than a sound which he had detected several times in examining patients with large ovarian cysts. He could not describe it better than by saying it felt as if something slipped, almost producing a noise. Of course it was nothing more than the movement of the cyst against the parietal peritoneum. He believed it had some influence in deciding the question of a previous peritonitis. Whenever it was present in his cases there had been no adhesions. When the sensation was absent adhesions had been found.

DR. SWAN M. BURNETT presented

A SARCOMA OF THE EDGE OF THE ORBIT AND THE
EYELID.

Also,

A MODIFICATION OF THE REFRACTION OPHTHAL-
MOSCOPE.

DR. RICHEY thought the modification ingenious, simple, and useful.

DOMESTIC CORRESPONDENCE

"POTASSIUM CHLORIDE."

(Kali Chlorici, Merck, Darmstadt.)

TO THE EDITOR OF THE JOURNAL:

I have read with great interest Dr. Pattee's article in THE JOURNAL of July 24, concerning potassium chloride. The notoriously bad results following the use of potassii chloras have induced me to make use of the milder and more efficient preparation of kali chlorici.

For some years I have used this preparation with satisfactory results. I have repeatedly endeavored to bring this remedy to the notice of the medical profession. In the *Medical News* of May 19, 1883, I called attention to its valuable properties, especially as a remedy in various forms of throat diseases. In the *Philadelphia Medical Times*, of July 28, 1883, I

again endeavored to bring it into notice, and lately, in the *New York Medical Journal*, of May 8, 1886, I have urged its employment in the treatment of diphtheria.

I have found it difficult to explain to medical brethren that such a preparation really does exist, and that it is very different, in the action at least, from the harsher and less reliable preparation of the chlorate. The use of kali chlorici in Germany has won for it great favor, and it has certainly proved itself more valuable than the older and rougher preparation of the chlorate.

I find the following a convenient formula for its use:

R	Kali chlorici (Merck's).....	3iv
	Syrup, simple.....	3vi
	Aquæ distil.....	3vi M
S.	3vi every hour.	

Very often the action of the chlorate of potash will seem decidedly poisonous, but the milder chloride will be found very useful and valuable. The important preparation is the one I always use.

W. THORNTON PARKER, M.D.

Newport, R. I., August 3, 1886.

BOOK REVIEWS.

DICTIONARY OF PRACTICAL SURGERY by various British Hospital Surgeons. Edited by CHRISTOPHER HEATH, F.R.C.S., Holme Professor of Clinical Surgery in University College. Vol. I. Abdomen—Lymph-Scrotum. pp. 970; Vol. II. Macroglasia-Zygoma, pp. 884. Bound in one large 8vo. Volume. Philadelphia: J. B. Lippincott & Co. 1886.

This dictionary, which is as good as Quain's "Dictionary of Medicine," is made for that much protected and long suffering individual, the busy practitioner. Under the editorship of Mr. Heath, and with so many good surgeons to assist him the work could not be otherwise than good. An extended notice of such a work is obviously out of the question.

A MANUAL OF PRACTICAL THERAPEUTICS, compiled with Reference to Articles of the *Materia Medica*. By EDWARD JOHN WARING, C.I.E., M.D., etc. Edited by DUDLEY W. BUXTON, M.D., etc. Fourth Edition. 8vo., pp. XIX, 666. Philadelphia: P. Blakiston, Son & Co. 1886. Chicago: W. T. Keener.

Thirty-two years have elapsed since the first edition of this work appeared. Necessarily many changes have been made in that time, in drugs, in medicine itself, in the manner of giving drugs. The book has been correctly named "A Manual of *Practical Therapeutics*," for it is essentially practical, but in no sense a mechanical work for mechanical men. There are no formulæ of impossible compatibilities; one drug is taken up, its therapeutic applications considered in as few words as possible, and the drug next in alphabetical order is taken up. It is well indexed, both by diseases and drugs.

FRACTURES AND DISLOCATIONS. By T. PICKERING PICK, F.R.C.S., Surgeon to and Lecturer on Surgery at St. George's Hospital, etc. 93 Illustrations. Small 8vo., pp. VIII, 524. Philadelphia: Lea Brothers & Co. 1887. Chicago: A. C. McClurg.

This is one of the Clinical Manuals for practitioners and students, which are being issued by the publishers, and thus far can certainly be placed at or very near the head of the list as regards its value. No one could expect that so small a book could be placed in competition with the classical work of the late Dr. Hamilton; but for all that it is an excellent book, of a most convenient size, well printed. The only possible objection to it and others of the series is that the blue of the cover is not fast. It is well illustrated, many of the illustrations being new and drawn from specimens in St. George's Hospital.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

BRITISH MEDICAL ASSOCIATION.—The fifty-fourth annual meeting of the British Medical Association seems to have been one of the most successful ever held. The Address of the President, and Addresses in the Sections were able, and most interesting. The visiting medical men from America were cordially received. "The proceedings," says the *British Medical Journal*, of August 14, "were greatly heightened in interest by the attendance of a delegation from the International Medical Congress, to be held in America, at Washington in September, 1887, to present an invitation to attend the Congress to the members of the British Medical Association. There have been some considerable internal dissensions among the organizers of this Congress, but it was very generally felt that this ought not to and could not prevent the invitation from America from receiving a cordial acceptance. This invitation, which was made at once in the name of the International Medical Congress by its President-elect, and of the American Medical Association by some of its principal officers, was received with that sincere and affectionate cordiality which both the purport of the mes-

sage and the sources from which it came already assured for it in advance. It lost nothing of dignity or of interest in the weighty and grave words of Dr. N. S. Davis, one of the oldest and most respected members of the profession in America, and one who holds very much the same relation to the American profession as Sir Charles Hastings long held to the profession in Great Britain. Dr. Davis was practically the founder of the American Medical Association, and is its most respected spokesman. The English profession may be sure that they will receive in America a welcome of unlimited hospitality, and of boundless kindness and brotherly affection. They will see there a great country and a great profession, which has sprung up and developed with a rapidity and to an extent which the world has never seen during the life-time of many who were present to hear the invitation. In our own country, Paget, Lister, MacCormac; in France, Charcot, Trélat; and in all the countries of Europe, leading representatives of science have accepted invitations to be enrolled on the list of Vice-Presidents. In America, the President of the United States, and the great officers of State, have signified their acceptance of the offices of Patrons of the meeting; and official recognition of the highest kind, such as is naturally due to a great gathering of medical men from all parts of the world, will be accorded to those who accept the invitation to attend the first great International Medical Congress which has ever been held in the United States."

MEDICAL INSPECTION IN BROOKLYN.—The Brooklyn commissioner of health, DR. ANDREW OTTERSON, has inaugurated in that city an admirable system of medical inspection and relief in the tenement-house districts, with special reference to the diseases of infants during the heated season. Ten physicians have been appointed, each assigned to a special locality, who are instructed to search for sick children needing attention and to care for them, furnishing medicine gratuitously where parents are unable to pay for it, and at a reduced price to those who can. They are to note the condition of premises and report where sanitary improvements are needed, give advice as to healthful manner of living, urge parents to take their children into the fresh air as much as possible, and give orders on the diet dispensaries for proper food when it cannot be obtained otherwise. The salaries of the physicians (\$75 a month) are to be paid out of the emergency fund. As a contrast to this beneficent movement in Brooklyn, the New York Board of appointment this year refused to allow the appropriation devoted last year to similar uses, with the result of a marked increase in infant mortality in the crowded districts of this city. — *Sanitary News*, August 14, 1886.

MEDICAL AND SCIENTIFIC NEWSPAPERS IN JAPAN. — From recently published statistics of the Japanese press it appears there are seven medical papers, with a monthly circulation of 13,514; nine relating to sanitary matters, with a circulation of 8195; and two on pharmacy. There are seven devoted to various branches of science.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM AUGUST 14, 1886, TO AUGUST 20, 1886.

PROMOTIONS.

- Lieut.-Col. David L. Magruder, promoted to Surgeon, with rank of Colonel, July 26, 1886, vice Brown, retired.
 Major Chas. T. Alexander, promoted to Surgeon, with rank of Lieut.-Colonel, July 26, 1886, vice Magruder, promoted.
 Capt. Henry M. Cronkhite, Asst. Surgeon, to be Surgeon, with the rank of Major, July 26, 1886, vice Alexander, promoted.
 Freeman V. Walker, of Georgia, appointed Asst. Surgeon, July 27, 1886, vice Cronkhite, promoted.
 Major J. C. Bailly, Surgeon, granted one month's leave of absence. (S. O. 111, Div. of the Atlantic, Aug. 17, 1886.)
 Major Geo. M. Sternberg, Surgeon, granted leave of absence for fifteen days. (S. O. 186, A. G. O., Aug. 12, 1886.)
 Major E. Bentley, Surgeon, granted one month's leave of absence, and at its expiration to report for duty as Post Surgeon at Little Rock, Ark. (S. O. 113, Div. Atlantic, Aug. 18, 1886.)
 Major W. S. Tremaine, Surgeon, sick leave further extended six months. (S. O. 187, A. G. O., Aug. 13, 1886.)
 Capt. L. Y. Loring, Asst. Surgeon, leave of absence granted him in S. O. 59, Aug. 2, 1886, Div. of the Pacific, extended two months on surgeon's certificate of disability. (S. O. 189, A. G. O., Aug. 16, 1886.)
 Capt. B. D. Taylor, Asst. Surgeon, when relieved by Surgeon Bentley to proceed to Jackson Bks., La., and report for duty as Post Surgeon. (S. O. 113, c. s., Div. of the Atlantic.)
 Lieut. Phil. G. Wales, Asst. Surgeon, relieved from duty in the Dept. of the Columbia, and to report in person at hdqrs. Div. of the Pacific for further orders. (S. O. 62, Div. of the Pacific, Aug. 9, 1886.)
 First Lieut. W. E. Hopkins, Asst. Surgeon, ordered from Ft. Lowell, A. T., to Angel Island, Cal., for duty as Post Surgeon. (S. O. 61, Div. of the Pacific, Aug. 6, 1886.)
 Lieut. Wm. C. Borden, Asst. Surgeon, assigned to temporary duty at Ft. Bridger, Wyo., during absence of Asst. Surgeon Crampton. (S. O. 100, Dept. of the Platte, Aug. 9, 1886.)
 First Lieut. Charles F. Mason, Asst. Surgeon, assigned to duty as Post Surgeon at Plattsburg Bks., N. Y. (S. O. 113, Div. Atlantic, Aug. 18, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING AUGUST 21, 1886.

- Stone, Dr. E. P., commissioned an Asst. Surgeon in the Navy Aug. 5, 1886.
 Wentworth, A. R., Asst. Surgeon, ordered to temporary duty, Navy Yard, League Island, Pa.
 Lippincott, G. C., P. A. Surgeon, ordered to Annapolis, Md., for temporary duty as member Medical Examining Board.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED AUGUST 14, 1886.

- Carter, H. R., P. A. Surgeon, granted leave of absence for thirty days. Aug. 12, 1886.
 Glennan, A. H., Asst. Surgeon, granted leave of absence for thirty days. Aug. 9, 1886. To examination for promotion, Aug. 12, 1886.
 Pettus, W. J., Asst. Surgeon, when relieved at Savannah, Ga., to rejoin station, New Orleans. Aug. 13, 1886.

CORRIGENDA.

In THE JOURNAL of August 21, in Dr. G. E. Frothingham's article on "Cocaine in Cataract Extraction," p. 205, 2d column, 5th and 9th lines from bottom, + 71 should be T + 1, and + 72 should be T + 2.

In THE JOURNAL of August 14, p. 193, second column, in the list of Vice-Presidents of the Section on Diseases of Children in the Ninth International Medical Congress, for Wm. G. Booker read Wm. D. Booker, of Baltimore, Maryland.

DIGITAL EXPLORATION OF THE BLADDER, WITH REPORT OF TEN CASES, INCLUDING TWO PROSTATOTOMIES.¹

BY WILLIAM T. BELFIELD, M.D.,

GENITO-URINARY SURGEON, COOK COUNTY HOSPITAL, CHICAGO.

The exploration of the bladder in the female by the finger, introduced through the dilated urethra is a recognized surgical procedure of long standing. By an incision from the perineum into the membranous urethra, a condition analogous anatomically to the natural structure of the female is artificially produced in the male; for the exploring finger can then be introduced at a point corresponding to the location of the urinary meatus of the female; that portion of the urethra which is solely a genital organ and peculiarly masculine—the penile portion—being thus avoided, the bladder of the male is thereby rendered quite as accessible as is that of the female. This method of exploring the bladder in the male by means of perineal urethrotomy—brought prominently before the profession as a systematic means of diagnosis some three years ago by Sir Henry Thompson and Mr. Whitehead—often affords the only means for the recognition and relief of obscure vesical disease. By it the surgeon is also enabled to differentiate between disorders of the kidney and of the bladder when all other diagnostic means, even the microscope, have failed; and he can often readily relieve a painful condition that has long been blindly and unsuccessfully treated under the comfortable and comprehensive designation of “cystitis.” This term cystitis, by the way, should be relegated—with jaundice and dropsy—from the list of diseases to the catalogue of symptoms; since it is apparently always secondary to some tangible abnormality in the urinary or pelvic organs or in the spinal cord. Yet simple, safe, and valuable as the operation is, it can be made unnecessarily, and even with disastrous results. Like many other surgical proceedings, it is safe only when the surgeon possesses not merely the requisite manual dexterity but also an intelligent comprehension of the conditions involved. It is the object of this paper to offer some suggestions, based on experience and observation, as to the indications for *not* performing, as well as for employing, this operation.

During the past eighteen months it has been my lot to make a digital exploration of the bladder, by perineal urethrotomy, in nineteen adult males. In seven cases the exploration was incidental to the performance of membranous urethrotomy for stricture and afforded no particular information; in the remaining twelve cases the operation was made as a means either of diagnosis or of treatment, or of both, as shown in the following brief résumé:

Case 1.—George G., 58 years old, came under my care April 29, 1885. Has had gradually increasing difficulty in urination for four years. Two years ago he had complete retention; was relieved by catheter. On that occasion the urine drawn was he says “like glue.” Some bleeding followed the withdrawal of the catheter. Since that time urination has been frequent, painful and straining; he often makes several unsuccessful efforts before the urine appears; is frequently compelled to use a catheter; urinates about every hour day and night. Defecation occasions severe pain in the perineum and penis. Has been treated for cystitis and for prostatic enlargement without appreciable improvement. On examination the prostate was found symmetrically and moderately enlarged; catheter shows 6 to 8 ounces of residual urine; the eye of the catheter is filled with clotted blood; a drachm or two of blood follows the withdrawal of the instrument. The urine becomes semi-gelatinous on standing a few minutes. With the microscope there are found some pus and many blood corpuscles. A diagnosis of villous growth from the prostate is made with entire confidence.

Operation May 1: The finger detected just to the left of the urethral orifice, springing from the prostate, a villous growth with a circular base about half an inch in diameter; and imbedded in its meshes two calculi as large as a pea and a bean respectively. Tumor and stones were removed and the site of the growth thoroughly scraped with the curette. Rather free hæmorrhage was controlled by hot water and pressure. Convalescence was uninterrupted; the perineal wound was completely healed on the 17th day. Patient resumed work. Urination was free and painless; he rose usually once during the night to evacuate the bladder. June 22 he observed for the first time a little blood at the end of urination; this was repeated several times up to the end of July, at which time I lost sight of him.

The interesting feature of this case was the diagnosis; the villous nature of the growth was predicted upon the tendency to hæmorrhage, the rapid clotting

¹ Read in the Section on Surgery, at the Thirty-Seventh Annual Meeting of the American Medical Association.

of the blood, but especially upon the gelatinous appearance of the urine after standing a short time; that it grew from the prostate was considered almost certain in view of the pain along the urethra and in the perineum.

Case 2.—C. G., 17 years old, was referred to me in October, 1884. For two years, he had had gradually increasing frequency and pain in urinating; for one year the urine had contained considerable pus and albumen. On examination I found no objective symptoms in the urinary or genital organs; subjectively there was pain and tenderness of the urethra and bladder neck; urination every half-hour day and night.

Diagnosis not certain, but *tuberculosis of the kidney pelvis* is suspected, though no bacilli were found in the pus examined at that time.

At my advice, he went in November as a forlorn hope, to Southern California. For three weeks after arrival he improved rapidly in both and general symptoms; then after exposure in the rain, a decided aggravation of the disorder ensued. The local physician assured the patient and his mother that there was no tuberculosis about the case and that complete and permanent relief would be obtained by opening the bladder. In April he returned to Chicago and I was requested to perform the operation, but declined on the ground that it would be useless; for I was now enabled to confirm the diagnosis of tuberculosis by the discovery of the characteristic bacilli in the pus expelled with the urine. Finally, however, when it became apparent that the patient and his friends were determined to have the operation performed by some one, I consented. May 18 I explored the bladder with absolutely negative results. A slight improvement in the local symptoms lasted for some weeks.

Examination November 21 showed nodular enlargement of the right epididymis, typical of tubercular disease. The patient's local symptoms were about the same as before, his general health somewhat worse. In this case, the important feature was the diagnosis, which was necessarily somewhat doubtful until the bacilli were discovered in the urinary pus; and even then the possibility that an additional undiscovered factor might be present—a vesical calculus or growth—was a reason for operation. The case illustrates the established but often neglected fact, that extreme irritability of the bladder and tenderness of the urethra can be caused by disease of the kidney-pelvis.¹ An unpleasant result was a persistent, though very slight perineal fistula, caused by my failure to remove the drainage tube until nearly three weeks after operation;

Case 3.—Michael H., 63 years old. Gives a history of cystitis for four or five years. Complete retention two years ago. Admitted to County Hospital, April 14, 1885, for retention; relieved by catheter. Was sounded for stone with negative result; the case was regarded as one of enlarged prostate, and the bladder

was irrigated daily. May 1 was transferred to my service; found him very weak, emaciated and feverish, temperature ranging from 101 to 104, pulse from 110 to 140; has had irregular chills for two weeks past. On examination per rectum I could detect no prostatic enlargement, but felt a sac about as thick as a lead-pencil containing numerous small calculi, and extending from the left apex of the prostate upward along the rectum as far as the finger could reach. My diagnosis was concretions in the seminal vesicle and consequent cystitis. As the patient's condition was critical I determined upon immediate operation.

May 1, with the assistance of Drs. Miller and Fenger, I explored the bladder. Upon inserting the finger into the bladder I found that the concretions were more plainly felt there than by the finger in the rectum. Hence we concluded that they must be contained not in the seminal vesicle, but in a diverticulum of the bladder. Yet it was impossible to secure a direct contact with the stones, as they were everywhere covered with mucous membrane. A little search revealed at the lower extremity of the mass, a slight depression in the surface of the bladder. The mucous membrane at this point was torn by the fingernail, which thereupon came into contact with a calculus. The opening was enlarged and calculi ranging in size from a pea to a hazel-nut were scooped out of the cavity, one after another, until seventeen lay upon the table. The patient rallied nicely from the operation; his pulse and temperature became nearly normal, and for two weeks I entertained, in spite of his previous condition, a hope that he might recover. At the end of the third week, however, he began to exhibit an evening rise of temperature, and he finally died June 12, six weeks after the operation.

Case 4.—John A., 38 years old. Was admitted to the County Hospital October 16, 1885. For over a year he has been compelled to urinate frequently and has had pain above the pubes and along the urethra. These symptoms gradually increased and were repeatedly complicated with retention of urine; during the last six months he has constantly carried, and frequently been compelled to use, a catheter. On admission he is attempting to urinate, with but little success, every fifteen minutes day and night; and complains of constant and severe pain, aggravated during urination, along the urethra, in the glans and behind the symphysis. The urethra is so tender that he yells with pain upon any attempt to introduce a rigid instrument. With a soft catheter it is ascertained that there is no decided stricture and that the entrance to the bladder is unobstructed. There is no prostatic enlargement; the urine contains a little pus.

Diagnosis: A tumor, nature unknown, though probably neither malignant nor villous, growing from the prostate.

October 23 I explored the bladder. The finger on entering the bladder pushed before it a smooth body which was found to be of doughy consistence, globular form, about as large as a walnut, and attached by a rather narrow pedicle to the upper margin of the urethral orifice.

The symptoms were thus clearly explained; for

¹ This patient, who passed out of my hands a year ago, died August 16, 1886. At the autopsy there was found some tuberculosis of both lungs and advanced tuberculosis of the right kidney, but little of the renal tissue remaining; the left kidney was enlarged, fatty, but not tuberculous; prostate and bladder apparently free from tubercles.

Until shortly before death there were no symptoms, subjective or objective, to indicate which kidney was the seat of the disease.

the tumor—suspended against the urethral orifice by its narrow pedicle—evidently acted like a valve; for while it was readily pushed aside by the catheter from without, it effectually prevented the escape of urine from within the bladder, and thus produced the symptoms of a tight stricture.

Query—Are there not possibly cases of similar nature circulating around among surgeons and labeled “spasmodic stricture”?

Presuming that it was a fibrous or mucous polyp, I inserted through the wound a small stone forceps with the intention of twisting off the pedicle. While I was introducing my finger alongside of the forceps in order to control its extremity, about half an ounce of watery fluid (which I then supposed was urine) escaped from the bladder. I then discovered that the tumor had disappeared; but by a careful search I found a very delicate membrane, evidently a collapsed cyst, resting against the bladder wall. As I could not seize it with any instrument at my disposal, I tore the sac as completely as possible with the finger nail.

For two days subsequently the patient suffered excruciating pain along the urethra; but his convalescence was unusually rapid, the wound being entirely healed on the 9th day. At first he was compelled to urinate every two or three hours, day and night; but this discomfort—apparently a mere habit of the bladder—gradually disappeared. For four months past his urinary functions have been perfectly painless and normal.

Case 5.—M. W., 38 years old, was admitted to the County Hospital November 3. For several months he had experienced pain and difficulty in urinating, alternating with incontinence. His urine contained much pus; his bladder was sometimes distended, and at other times empty; there was no stricture nor prostatic enlargement. For several weeks before admission he had suffered from irregular chills followed by fever and sweating; his general health was much impaired; his condition in short was that described as “typhoid.”

It was evident that he was suffering from cystitis and pyelitis, though I was unable to recognize the cause; nevertheless I considered perineal urethrotomy justifiable as a means of relief from this condition.

November 14 the bladder was explored and drained; nothing abnormal was found. Yet the expected results were attained; the chills and fever ceased, pulse and temperature became normal, the appetite returned, the urine became clear, in short the cystopyelitis subsided. After his convalescence from the operation when the patient again began to walk, I discovered the cause of his cystitis—namely an incipient transverse myelitis. Had he not been confined to his bed upon admission to the hospital, I would probably have detected this lesion; yet I would just as certainly have performed the operation, since without it he would soon have died of suppurative nephritis, the danger of which was now removed.

Cases 6, 7 and 8 were unfortunately instances of malignant tumor of the prostate and bladder. Two were men aged 69 and 58 years, respectively; in each of these the diagnosis—which was rendered al-

most certain by the history and physical examination—was made absolute by the discovery of numerous atypical epithelial cells in the urinary sediment under the microscope. The older of these two men was already bedridden from exhaustion when I first saw him; in this case I made perineal urethrotomy, and inserted a drainage-tube merely to obviate the agony of frequent urination. Such great relief was secured that the drainage was maintained until his death, three months later.

In the second case the patient was seen at an early stage of the malignant disease. Having located the growth in the left lobe of the prostate, I explored the bladder to ascertain the feasibility of an attempt at removal, intending, if excision of the neoplasm with the cautery seemed practicable, to make also a supra-pubic cystostomy for additional facility of manipulation. I found, however, that the growth not only involved the left lobe of the prostate, but was also prolonged, as a small, firm ridge, along the posterior wall to the vertex of the bladder. I therefore made no attempt at removal. The wound healed readily; the patient is still—four months later—able to walk, though steadily sinking under the malignant disease.

The third case of prostatic cancer presented an instructive feature. It was that of a man 31 years old, admitted to hospital with a violent and fetid cystitis and almost complete retention of urine. Per rectum the prostate was found greatly and irregularly enlarged, hard and knotty, making the diagnosis easy. Although large instruments readily entered the urethra as far as the prostate, I was unable to pass even the smallest catheter over the prostatic obstruction. I performed membranous urethrotomy and inserted a drainage-tube into the bladder.

Almost complete suppression of urine ensued; and in spite of fomentations to the loins and pilocarpine internally, the patient died of uræmia on the fourth day. At the autopsy there was found an epithelioma involving the prostate and floor of the bladder; the vesical walls were enormously hypertrophied, the kidney calyces were greatly dilated, and there was a pipe-stem calculus in the left pelvis. This case exemplifies the danger—not yet sufficiently recognized—of emptying the bladder in cases where, from long obstruction to the exit of urine, the bladder walls have become hypertrophied and the kidney pelvis distended.

Case 9.—X. C., 59 years old, was admitted to hospital February 3, 1885, in the last stages of chronic cystitis, from which he had suffered for fifteen years. He had repeatedly had complete retention of urine; for five years has been obliged to urinate every hour or oftener, day and night, and for more than a year past has been practically unable to void urine except through a catheter. On admission he was in a typhoid state and suffering from irregular chills, fever and sweats. After vainly trying for several days to improve his condition by washing out the bladder, I made perineal urethrotomy February 9, and drained in the usual way. Immediate and complete relief was secured; on the second day his temperature became and remained normal.

Finding the cause of the cystitis in an immense

myoma—or so-called hypertrophy—of the prostate, I seized the opportunity to execute a plan which I had long cherished, namely, to make an artificial channel through the obstructing portion of the prostate.

Accordingly, two weeks later I reopened the perineal wound and with the galvano-cautery made a channel through the prostate sufficiently capacious to admit easily an ordinary lead pencil. To my surprise and gratification the patient showed absolutely no reaction, his temperature never exceeding 99° F. After the wound healed he easily retained urine three to four hours, and passed water without pain and without a catheter; the residual urine was reduced from eight ounces to half an ounce, showing that the bladder almost completely emptied itself; the urine was quite clear, even after standing. In short, he left the hospital April 3 a new man.

In consequence of the habitual retention of a little urine, I directed him to use the catheter once daily, an injunction which, after returning to his home, he usually ignored. As a consequence he had on two occasions during the following summer slight indications of cystitis, which, however, quickly subsided when the catheter was used once or twice daily.

September 12 he suddenly manifested signs of acute uræmia, of which he died, nearly seven months after the operation.

The uræmia was explained at the autopsy by the discovery of very small, contracted kidneys. I also secured the bladder and prostate, which are here submitted for your inspection.

Case 10 was a man 68 years old, with the usual history of cystitis from prostatic enlargement, extending over seven years. Although he was in a very exhausted condition, I attempted to repeat the operation of channeling the prostatic obstruction practiced successfully on the former patient (Case 9). In the midst of the operation the battery failed, so that my design could not be executed. The patient's ability to urinate and his comfort were decidedly increased by the incomplete operation; but his health did not improve, and he died some two months later.

The value and safety of digital exploration of the bladder through the membranous urethra as a means of diagnosis and treatment, are so clearly exemplified in these cases that I shall expend no time in expatiating upon them. I would merely remind you that the cases are in no wise selected ones, but are recorded as they successively occurred; that the majority of the cases belonged to that class of ill-conditioned individuals who drift into the wards of a large charity hospital; and that five of the ten were brought into the hospital in an apparently hopeless condition, to die.

Of the ten, three died within two months after operation; in one of these—the case of prostatic cancer, where death ensued in four days, from uræmia—the fatal result was unquestionably hastened and directly caused by the operation, though without operation this man could not have lived many days. In the two other fatal cases—where death occurred some two months later—it is just as certain that the operation prolonged life; and had it been performed a year or two earlier, before the patients had become

so exhausted, it would have been extremely beneficial.

As essential preliminaries to a diagnostic exploration of the bladder, I would adduce two considerations:

1. It should not be performed as a diagnostic measure until it is reasonably certain that the seat of the difficulty is in the bladder, or until all other and less radical diagnostic means, including the microscope, have been exhausted; otherwise it may yield only disappointment and regret to both surgeon and patient. For it must be remembered that an irritable condition of the bladder can be produced by causes without as well as within this viscus, such as stricture of the anterior urethra, tuberculosis or calculi of the kidney-pelvis, etc. In such cases the morbid symptoms may be exhibited chiefly or exclusively by the bladder, while the lesion lies chiefly or exclusively elsewhere. As examples I would mention my own case of tuberculosis, and the two cases of exploration of the bladder which I have seen performed by other surgeons; in both of these the operation was ill-considered and fruitless, since in each the lesion evidently lay in the renal pelvis.

2. The operation should never be performed until the bladder has been accustomed to complete evacuation, by catheter or otherwise. If in consequence of a tight stricture or prostatic obstruction, the bladder is much hypertrophied, membranous urethrotomy is dangerous, not from a probability of urinary extravasation, but simply because a cysto-pyelitis of more or less gravity—possibly even anuria—usually follows the sudden removal of the accustomed high pressure in the bladder and kidney pelvis. Examples are found not only in my own fatal case of anuria, but also unfortunately in the daily introduction of catheters for retention, division of tight strictures, lithotomies, etc. Therefore, before the bladder is explored in a case with tight stricture, prostatic enlargement or other cause of vesical hypertrophy, the bladder should be gradually accustomed, in the course of weeks, to complete evacuation; the stricture should be enlarged; or the prostatic obstruction should be overcome by the habitual use of the catheter until all residual urine is withdrawn. Then, and *not till* then, can the surgeon rest assured that digital exploration of the bladder from the membranous urethra, whether it afford much or little benefit, will at least be safe and devoid of injury.

ON THE RADICAL CURE OF INGUINAL HERNIA. A REVIEW OF THE EXISTING STATUS OF THE OPERATION, WITH REMARKS ON ITS PAST HISTORY.¹

BY JOHN B. HAMILTON, M.D.,

SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE, WASHINGTON, D. C.

Few subjects are more attractive to the surgeon than that of hernia, whether viewed from the standpoint of pathology or that of surgical therapeutics. The ablest surgeons in past ages, as I shall presently

¹ Read before the Chicago Medical Society, August 16, 1886.

show, devoted much of their attention to the subject, and although time has passed, and tome and thesis become dusty with age, and in many cases the theories themselves misty with the changes of time, and in others laid forever at rest by the solid anatomical facts hurled against them, there has been a golden thread of truth extending from the earliest time to our day. But this thread, however bright and shining, is only a thread; and while some things are proved concerning the guiding principles of the operation, yet the disease continues to afflict mankind, and until the ushering in of antiseptic cleanliness in all operations, the weight of surgical opinion in our day was against the attempt to cure hernia. Several such periods have come and gone in the history of this operation, and while nothing in history of the past may seem to warrant the disturbance of the present surgical lethargy, yet it is worth while to get our bearings, as the mariner takes a reckoning to find out where he is and to determine his future course.

Dr. Morell Mackenzie must have been secretly thinking of hernia when he commenced writing that able article in a recent number of the *Fortnightly Review*, entitled "Is Medicine a Progressive Science?" Let us then get our bearings; take from unused shelves the musty records of former surgeons, and having found where we are, let us see if some headway may not be made to remove the reproach. That the disease is sufficiently prevalent to be of interest Heaven knows. Dr. Baxter's tables show that out of 334,321 recruits and substitutes examined by the recruiting officers during the war of the rebellion, more than 17,000 were rejected on account of hernia. George Hamilton, of Liverpool, estimated that in England alone there were one and a quarter millions of persons suffering from hernia, and 88 per cent. of these hernias are inguinal. The London Truss Society, during the first twenty-eight years of its existence, had issued over 83,000 trusses to the ruptured in the city of London alone, and from information received by me since this paper was commenced, I find that two factories in the city of Philadelphia manufacture and sell from 216,000 to 250,000 trusses per annum! Nor do all the ruptured wear even this badge of incurability. Think of all the old incarcerated hernias and concealed hernias, where trusses cannot be worn, and where from fear of pain or from penury the patient will not or cannot buy a truss! Let surgery, then, apply itself anew to the task before it; for there is yet a world to conquer. Let it not be dismayed by the fatalistic evolutionists who hold that the weakness of the abdominal walls is a certain evidence that man has been evolved from beasts which did not walk erect, and that in the fullness of time when man has been long accustomed to walk upright, the abdominal walls may become tougher, or enveloped in a cartilaginous or bony case. It may be considered a little impatient, but I for my part have no desire to wait. I wish to stimulate experiment and inquiry, and when the dawn of that time shall come for which evolutionists sigh, when man shall be physically perfect, and it shall be said of this beautiful city, as of Troy—Chicago was—let it also be said of this disease: there was once a ques-

tion as to how to cure a very painful and fatal disease, now happily obsolete, but the surgeons of that day settled it. This much is introductory; let us now briefly look up the history of the past, which, thanks to the labors of Sprengel and others by whom it has been compactly and succinctly stated, the task is an easy one.

HISTORY.

Celsus was the first surgeon to fully define the tunics of the scrotum and testicle, and he had definite ideas about the operation for the cure of hernia. He used cauterization and a bandage, probably a spica. Sprengel thinks Celsus borrowed his notions from Alexandria, for Leonidas of Alexandria had exploded the doctrine of the rupture of the peritoneum, and taught the practice of cauterization; he also in some cases scarified the parts and used astringents.

Paulus, who followed Celsus in almost paraphrastic terms, did not mention him, and the able translator of Paulus (Francis Adams), remarks, "But when did a Greek writer ever acknowledge himself under obligations to a Roman?" Thus, if you will pardon the digression, you will see that the Eastern custom of ignoring the progressive West, of which custom some of you may have heard of late, is of rather ancient date.

The Arabians, Hali Abbas and Ali, the son of Abbas, used astringents as topical applications, and in severe cases they practiced the actual cautery.

Ligature of the sac had been practiced from an early day, and Paulus and his Arabian followers described the operation. The red hot iron for many centuries was the favorite remedy.

Maupas was the first who recorded himself in favor of making a straight incision directly through the rings, performing a gastrorrhaphy, and stitching up the wound.

Lafranc, who flourished in 1296, favored castration according to the ancient methods, and the fastening of the stump as a plug in the wound. He, however, had three methods, one the thrusting of red-hot needle points into the tissues about the hernia, and he invented the first compression forceps, or clamp. Guy de Chauliac, while criticizing the methods of his predecessors, and also that of a certain Bernard Metis who, before completing his incision, tied the cord with a gold thread, the modern point Dore, still believed in the caustic, and occasionally the arsenical paste. He recommended rest in bed and strong compression. It was desirable, in the opinion of surgeons of that period, to provoke suppuration at the ring.

The method of operating for the cure of hernia being nearly always accompanied with ablation of the testicle, now fell into disuse, and quacks alone practiced any of these operations. A traveling Spanish hernia-cutter was brought to the notice of Alexandre Benedictus, who performed some happy cures by the use of a silk seton, fastened to an ivory button. The same inhabitants of higher Italy who were celebrated in the Middle Ages for stone-cutting, were also very successful as traveling herniotomists, if contemporaneous accounts may be believed, and the

methods were kept a profound secret; but as late as 1633 Jean Baptiste Cortesa relates that he saw at Messina a certain Ulysse de Norcia apply a caustic substance, the parts consumed by it, and a very deep scar result. Joseph Covillard saw a "vagabond" cure a hernia by caustics and the ligature. (Sprengel).

Some of these peripatetic herniaotomists, after opening the sac, replaced the testicle in the abdomen, and drew the ring together with a gold thread. Scultetus relates that in his time the anabaptists frequently performed this operation in a similar manner. Fallopius practiced the ligature and castration. He did not object to the methods of his predecessors, but limited and modified them. He restored the gut after incision, by taxis and the use of oil of rose with white of egg; he used gold thread when he ligated the cord, and he scarified the rings. Ambroise Pare was the first to absolutely abandon castration. He used astringents, a bandage with iron filings to the surface as a counter-irritant, and powdered iron in the wound. He performed gastrorraphy in aggravated cases, and introduced a gold wire to separate the cord from the intestines.

About this time the treatise of Pierre Franco appeared, which in the light of modern anatomy once more dissipated the ancient error that hernia was always accompanied with a rupture of the peritoneum.

Freytag, a Zurich surgeon, was the first to practice dilatation of the rings in strangulated hernia, having first made incision. He then attached the peritoneum to the ring with numerous sutures.

Abraham Cypriaan, of Amsterdam, systematically dilated the rings with the finger until reduction was effected in the case of strangulated hernia, then with a two-edged knife he separated all the tissues about the ring and canal.

Nicholas le Quin, of Paris, and his nephew Antoine le Quin, appear to have introduced the truss about the year 1680, although the spica bandage had been used from the earliest times. In the time of Louis XIV operative procedures by the faculty had once more fallen into disuse, and the quacks reaped a harvest. A prior of Languedoc, named Cabrieres, communicated to the monarch under promise of secrecy during his life time, an infallible mixture which was never-failing in its power. This secret, when brought to light, was found to consist in the administration of muriatic acid diluted with red wine, and the external application of a pitch cerate under pressure.

Dionis wrote a thesis on this subject in which he recommended the opening of the sac with caution; he taught the principle of dilatation of the ring, and he tied the omentum. After the operation he introduced into the ring a large dossil soaked in yolk of egg and oil, kept it in place by a compress of charpie adjusted by a spica bandage.

Vauguyon was a close follower of Dionis, but he described the technique of the operation in more detail. He used the grooved director, not only for raising the tissues for division, but also for dilating the ring. He, after the restoration of the intestine, scarified the ring, and applied a bandage like Dionis. The long controversy as to whether the peritoneum

was really ruptured or not, was not settled until the beginning of the eighteenth century.

Michel Louis Renelaulme de la Garanne, while insisting there was a rupture of the peritoneum, operated in all cases except those of incarceration, by the operation as performed by Dionis; he used in addition to the ordinary bandage, a suspensory bandage. This was, many years later, brought forward by Mayor as a new procedure.

While French surgeons had thus come to follow a definite line of practice in these cases, the rest of the world, so far as known, still followed the Celsian plan of castration with cauterization.

Françoise Wiedeman, in 1719, was the first German to defend the new treatment of hernia adopted in France at this period. Jean Henry Freytag, of Switzerland, in 1721 rejected the castration and as well the point Dore. He still favored the scarification as practiced by his father, Jean Conrad Freytag, and recommended the excision of the projecting portion of the omentum, when necessary.

Mauchard in operating recommended that the bistoury be held flatwise (after the sac had been opened carefully), and he did not raise the membrane with the cellular tissue, when he had pierced the peritoneum, he introduced a sound, lifted the membrane and examined the state of the intestines. He then scarified the ring, and tied the sac with a waxed thread.

Heister recommended a truss, which, upon reference to the plate, is seen to be an oval pad attached to a strap, evidently intended to buckle around the waist.

He approves of Petit's operation; by this operation Heister says Petit cured a "tailor who was well within five days of the operation." Heister, however, advises that the bandage alone be trusted in large hernias. Incarcerated hernias he endeavored to reduce by the taxis, and having done so, he applied the "spica bandage, which should not be left off by the patient for many years, and if he be old, it should be worn during life. I have sometimes known a clyster of the smoke of tobacco succeed in relaxing the parts, when others have failed." "A large clyisma fumosum," he says, "of the common English or weak tobacco was injected into a poor patient under this disorder, but with no effect, but the smoke of strong Virginia tobacco quickly gave the patient a stool, and the prolapsed intestines soon returned into the abdomen of themselves." Heister, it is to be observed, when he did operate, anticipated certain so-called antiseptic precautions, by the cleanliness he required, and the shaving of the groin as preliminary to the operation. He always opened the sac and returned the hernia, without division if he could; if practicable, he divided the ring with care and applied the pledget or dossil of lint and a spica bandage; but then, as now, there were many attempts to escape the knife, the bandage, and the truss, and John Douglass states, in his "Syllabus of Chirurgical Operations," that a man named Little-John made great reputation throughout England by a secret remedy for which he was paid five thousand pounds by King George the First, who also added to this sum an annual pension of five hundred pounds.

When this remedy was promulgated, it was found to be cautery with sulphuric acid; and when the granulations sprung up they were touched with the *lapis infernalis*. A bandage to retain a plaster on the cicatrix completed this rather too highly appreciated discovery. If Little-John had lived in this day he might easily have increased his emoluments by starting a "sanitarium." We recognize this cauterization plan as an old acquaintance. And so the changes have rung, the same old story with but few variations from Celsus down. I will not weary you with continuing in this history an account of the methods of Alexander Monroe, Jean Georges Wagner, of Lubek, Lafay, Samuel Sharp, and Tacconi, for they were all simply modifications of the preceding plans. It was not until near the middle of the eighteenth century that surgeons began to cut off the gangrenous portions of intestines in cases of strangulated hernia. Claud Amyand, Montabourg, Peyronie, Ramdohr, Mery, were among the first to practice and recommend this procedure.

The glance we have thus given at what may now be termed ancient surgery of hernia, shows clearly enough how little may be hoped for as new, and yet how infinite the variations of the few fixed principles. If I do not quote, among the moderns, Percival Pott, Sir Astley Cooper, Benjamin Bell, Mohrenheine, Barthol and Saviard, Robertson, Dessault and Cline, it is simply because these excellent surgeons, some of of them masters, simply threshed the old straw. The Spanish surgeon Antoine de Gimbernat, in his "new method" of operating in crural hernia, Madrid, 1793, did develop some originality in description of the anatomy of crural hernia, but the field seemed to be worked out. Little change in opinion or sentiment took place until about 1840, when the method of creating inflammation of the whole canal by injection was again brought into notice, but it will now be more convenient and easy to follow if the different operations are adverted to seriatim.

Castration, first proposed by Celsus, and, as seen in the foregoing section, followed by surgeons for several centuries, has been long abandoned, although in cases where the hernia co-exists with disease of the testicle, as in the case reported by Nott, of Mobile, in 1847 (in which the lead wire was used), castration may very properly be an accompaniment of the operation.

Cauterization was formerly used by the Moxa to the surface, by red-hot irons, and by red-hot needles thrust into the tissues, and by mineral acids. Almost every known caustic has at some time or another been used for the cure of hernia. The galvano-cautery was proposed by Dr. John C. Minor, of New York (*Am. Jour. Electrology and Neurology*, 1879).

Topical Applications.—These have been the favorite remedies of charlatans in all ages, and have been occasionally used by the faculty, but being utterly unscientific in principle, are now abandoned.

Ligature of the Sac.—This operation is now practiced in connection with the so-called "antiseptic" operation, but in the modern operation the sac is opened, while in that of the ancients the sac was frequently ligated without opening. Ambroise Paré is

erroneously given the credit of the priority in this procedure. Malgaigne speaks of various kinds of ligature, including catgut. The elastic ligature has been brought forward. Molliere, in "Memoires Société des Lyons, 1877," proposed to occlude the neck of the sac by the elastic ligature. His conclusions were that the ligature of the sac was usually necessary and gradual ligature was the best method, and, in passing, it is proper to revert to the fact that Paulus Ægineta proposed and practiced sac ligation. Gal-laud, in 1878, favored the elastic ligature.

The Royal Suture.—The sac being entirely exposed, it was raised and stitched, after which the portion outside the suture was cut away. The term "royal" is somewhat whimsically said to have proceeded from the fact that the King's subjects were saved thereby.

Scarifications.—This practice is a very ancient one, and has been occasionally practiced down to a very recent date, with excellent results. These scarifications were at first practiced on the sac alone, but finally on the pillars and the entire canal. Dr. G. N. Fitch, of Chicago, in 1845 scarified the neck of the sac and produced a cure (*Indiana and Illinois Medical Journal*, N. S., Vol. IV). Guerin was probably the first to practice subcutaneous scarification. The so-called Heatonian method has, as one of its advantages, that the tissues about the pillar and canal are punctured.

Invagination (a) Without Suture.—This practice has for its object the occlusion of the inguinal ring by the fascia and sometimes by the integuments. Leroy D'Etoilles proposed invagination without suture, the invagination to be retained by a plug of rubber and retained by a bandage. Aitchison, in the *Indian Lancet*, September 15, 1860, proposed to invaginate the scrotum by a rubber tube carried into the ring by a solid plug. The plug was then to be withdrawn and the tube filled with air and retained with a bandage. This method he claimed could be used with or without suture, but this procedure was in fact long antedated by the truss pad of Dr. P. H. Cabell, of Alabama, who had constructed a truss pad with what he called a "finger-like process." (*Virginia Medical and Surgical Journal*, vol. iv, 1855.)

Invagination (b) with Suture has been practised for a longer period, and has been very successful. It in principle forms the basis of many of the more famous operations, such as Gerdy's and Wutzer's. In Gerdy's operation the scrotum is invaginated on the finger and pushed into the ring. A double-threaded needle is thrust into the bottom of the cul-de-sac, brought out through the abdominal parietes, the needle withdrawn, reinserted at a little distance, withdrawn and the threads tied. This cul-de-sac, if left to itself, would prove a nuisance on account of the retention of moisture, and the skin was therefore denuded of its cuticle by repeated cauterizations with ammonia, and when granulations sprang up the surfaces were made to adhere by pressure. Bransby Cooper proposed to destroy the cuticle of the invaginated portion by actual cautery at a single operation. This method has fallen into disuse, although occasionally revived in our time. The late Dr. Geo. T. Allen, of Springfield, Ill., reported fifty cases cured by what

was practically Gerdy's method. (Trans. Illinois State Med. Soc., 1867-8.) Wutzer proposed to invaginate the scrotum by a wooden plug having a curved needle at the end. After the tissues were invaginated and the needle thrust through the tissues, a fenestrated metal plate was placed on the outside, with the needle projecting through the fenester, and clamped down tightly by means of a screw at the end of the plug. The apparatus is kept in place for about a week and a truss worn for some months. In Wutzer's first series of cases there were fifty-seven cases and no deaths. This operation was very popular in its day, but is now superseded by a method which might well be termed the combination method, by which I of course refer to Wood's method, which not only invaginates the fascia but draws together the pillars. While all these methods have their greatest success in small herniæ and bubonocèles, yet both Gerdy's and Wutzer's are absolutely valueless in those which are so large that an ordinary invagination will not occlude the opening. As Wood's operation is so recent and so well known, I will not in the presence of this audience stop to describe it. Mr. Wood's first case is recorded in the Transactions of the Medical Society of King's College, 1857-8.

Lawrence, who wrote the well known treatise on hernia, is frequently but erroneously given the priority of suggesting the drawing together of the inguinal rings by suture. The priority is probably due to those ancient surgeons who operated by incision through the canal. The varieties of suture used are almost endless, and it must provoke a smile to see in every country this operation when performed by any of these sutures described as new. In our country we point with pride to the fact that Physick recommended animal sutures. Levert, Nott and Gross used lead and silver wire, but it is known that Rhazes, the Arabian, described sutures made of harp or lute strings, with which he stitched wounds of the abdomen, and that there is no doubt that metallic suture wires of the less noble metals are really contemporaneous with the gold threads. To prevent the alleged untwisting of the catgut ligature, MacEwen, of Glasgow, in 1880 proposed to soak them in chromic acid.

Wood's operation has lately taken a new start by reason of the greater care in making incisions; insuring cleanliness; apposition of the parts, the use of germicide solutions and the excision of air from the wound. Dr. H. O. Marcy, of Boston, on October 11, 1871, reported cases treated by this method. Prof. Fayer, of Calcutta, in *Medical Times and Gazette*, April, 1872, reports fifty cases, of which forty-two were cured. Prof. Annandale and Sir William MacCormac give the priority to Dr. Chas. Steele, of Bristol, but Dr. Steele's first case was reported in the *British Medical Journal*, Nov. 7, 1874, more than two years after those of the Boston surgeon.

Marcy and Isidor Israelsohn are undoubtedly the pioneers in this application of antiseptic surgery.

Dr. Raye, of Calcutta, in the Trans. Med. Soc. of Calcutta, 1883, reports sixteen cases with twelve cured, one died, and two relieved, one under treatment on the date of the report. Swinton Edwards in 1884 reported three cases cured by this operation. He

used drainage, iodoform, gauze packing, and an elastic bandage.

In a discussion in the Liverpool Medical Institution in 1883, opened by Mr. George Hamilton, Dr. Alexander stated that he had performed the radical cure thirty times without any death. Mr. Banks stated that he had operated on more than fifty cases, but preferred wire to catgut. Mr. Puzey thought that the patients should be kept in bed for a considerable time, as if the patients got up too soon the tumor reappeared. This caution, in my judgment, is a necessary one, for in one of my own cases operated upon in May, 1886, at the Providence Hospital, Washington, an inguinal hernia was converted into a bubonocèle by the reopening of the internal ring. The patient in this case was allowed to get out of bed as soon as the wound was healed.

In a debate on the radical cure of hernia in the Academy of Medicine in Dublin, March 12, 1884, there was entire agreement both as to the propriety of the operation and of the excision of the sac. As to the general results of Wood's operation, Mr. Wood himself reports that out of 339 cases without special antiseptic precautions, and with wire sutures, ninety-six were cured, seven died, and fifty-nine failed; in the remainder the result could not be ascertained. The proportion of the unknown cases was presumably in about the same ratio. Nussbaum states that in half his cases the hernia returned, and in those reported by Leisrink one-third returned. There can be no doubt, then, that while much good has resulted from the operation, there is yet much needed to perfect its details. I wish it understood when I speak of Wood's operation, I mean as at present performed; that is, the "open" operation. Dr. Robert Abbe, of New York, recently reported twenty-one cases of this operation, with two deaths; in one case, however, the death was due to suppuration following an operation for varicose veins of the leg, which had been operated upon at the same time. His cases were too recent to give any account of the permanency of the cure.

One modification of Wood's operation has been proposed by Mr. W. Dunnett Spanton (*British Medical Journal*, Dec. 11, 1880), which consists in bringing the pillars together by means of a corkscrew wire mounted on a handle. A small puncture being made from above, the wire is placed in position, and forced down by a screw motion, the screw entering the pillars alternately. Mr. Spanton has operated on thirty-four cases with the screw and catgut suture, with no deaths. This proceeding differs little in principle from that practised by Dr. Grenville Dowell, who used a needle with a deep curve, and brought the pillars together by suture. Dr. Dowell reported in his book published in Philadelphia, 1876, ninety-six operations by nine different operators with a result of eighty cures and sixteen failures.

Accidents may follow Wood's operations as well as the others, such as sloughing, peritonitis and tetanus. On this last point Surgeon-Major French reported (*Indian Annals of Med. Sci.*, 1876) that two of his six cases were followed by tetanus. He thinks it likely that the climate may have been at fault. From

the statistics which I have had compiled from official reports on file in the Marine Hospital Bureau at Washington, it appears that in Calcutta for the year 1884 there were 1,137 deaths from tetanus, out of a total number of deaths from all causes of 12,823—nearly 9 per cent.; so there really seems to be more than a conjecture back of Surgeon-Major French's suggestion. The record by months is as follows:

TETANUS IN CALCUTTA, INDIA, 1884.

	Deaths from tetanus.	Total deaths from all causes.
January.....	64	919
February.....	61	964
March.....	114	1,516
April.....	105	1,709
May.....	98	1,332
June.....	71	797
July.....	85	7-9
August.....	101	785
September.....	102	816
October.....	112	869
November.....	115	1,260
December.....	89	1,127

Total for year..... 1,137 12,823

Percentage of deaths from tetanus to total deaths nearly 9 per cent.

"In Sweden an 'improved' operation for the radical cure of hernia has for some time past been practised by Drs. Svensson and Erdmann, surgeons to the Sabbatsberg Hospital at Stockholm. A ligature is applied to the neck of the hernia, and the sac is cut off below the ligature, the contents being previously examined by means of an incision into the sac and returned; or if only omental, excised, together with the sac. In congenital herniæ the upper part of the sac only is removed, and where the large bowel is included in the hernia and adherent to the sac wall, this, after being separated from the surrounding tissue, is returned together with the large intestine, and the rents of Poupart's ligament united by sutures.

"The dressing employed is iodoform and boracic acid, the wounds being washed with sublimate solutions. Since this has been substituted for carbolic gauze, abscesses, which used to occur frequently, have become rare. Of the forty-eight cases thus operated on, none of which were selected, thirty-eight were permanently cured; at least, no return of the hernia occurred within six months; and in the cases where a return did take place, which amounted to 20 per cent., the condition was very much less painful and distressing than it had been previous to the operation.

"Sabbatsberg Hospital has now been opened six years and a half, and during that time 300 cases of hernia have been admitted, about 200 of these being operated on with the knife, a milder procedure, consisting of alcoholic injections, being employed in most of the earlier cases.

"Not a single case proved fatal, though some of the herniæ were very large, some reaching within three or four inches of the knee." (*Med. and Surg. Rep.*, Philadelphia, 1886, ix, 115.)

In regard to the necessity for the recumbent position in the after-treatment of these cases, it should be the rule, and neglect of this rule seems to be the

cause of failure in many cases of recurrence. Ravin, indeed, many years ago proposed position as the only rational means of cure, applying the principle that any cavity in the body, when unused, became filled up, or its walls agglutinated by a mild inflammatory or adhesive process.

Two other methods of treatment, each popular enough in their day, I will not stop long to discuss. I refer to the injection, and the seton through the canal. Velpeau, in "Nouveau elements de Medicine operative, par A. L. M. Velpeau, Paris, 1839," stated that in the application of the fact that iodine exerted a wonderfully curative influence on serous membranes in general, as instanced in hydrocele, he had used injections of iodine for the radical cure of hernia in 1835. He again used it at the Charity Hospital in 1840, and this method being a great advance upon those then in vogue, became the favorite one in Paris. It was used in America by Pancoast of Philadelphia in 1836, who claims priority; by Dr. William Jayne at the Penitentiary in Illinois in 1840, and a few years later by Heaton, of Boston, who changed the fluid finally to the fluid extract of quercus alba, but for many years kept his remedy a secret, for which he was tried by the American Medical Association. After Velpeau all Paris began to use iodine injections, and new trocars and canulas figure in the reports and theses of the period. Nélaton, Ricord, Jobert, Maisonneuve and Follin invented "new" trocars. Some opened the sac with a bistoury, and others, as Jobert, plunged the trocar directly into the sac. The statistics were, as usual, at first highly favorable, but finally deaths from peritonitis began to be frequently noticed, and the operation became somewhat restricted in its application. Heaton's injection being milder in its operation, and injected into the pillars and aponeurotic fibres instead of the sac, still survives, having been, as one may say, rejuvenated, by the twisted and altogether wonderful syringe of Warren.

Dr. Luton, of Reims (*Bull. Gén. de Thérap.*, 1877), proposed the injection of 10 to 15 drops of salt water.

The introduction of the seton is probably due to Rattier in 1835, but, as may be gathered, most claims of priority, in the present state of literature, are somewhat problematical. Dr. J. W. Riggs, of New York, in 1858, revived the seton and invented a needle for that purpose, as did Dr. Armsby, also of New York. Dr. J. M. Carnochan (in *Am. Med. Gazette*, vol. ix, 1858), reports cases cured by the "Riggs method," and Dr. R. Thompson reported a "new" instrument, carrying the seton through the inguinal canal, to the Ohio Medical Society in 1859, but the seton, for some reason or another, has gone to join the iodine injection, and the acupuncture practice of Bonnet (1837). Various other methods of plugging the ring are recorded, the autoplasty of Jameson, of Baltimore, Langenbeck and Graefe, and finally the testicle itself. Dr. Chas. T. Hunter recorded a case where by the patient constantly pressing the testicle up into the ring it became fastened there, and the patient was cured. Dr. Hunter thought this a unique case, but Michel (*Ann. Jour. Méd. Sci.*, Oct., 1878) speaks of this as an old Spanish method. It was not

however, peculiar to Spain, although Henry Mo-miehm, writing in the early part of the seventeenth century, calls it a Spanish method, for both Garengeot and Scultetus in condemning it mention it as a recognized surgical procedure.

Let us pass the operations of Mayor by ligatures fastened on sponges, and his triangular "cravat" bandage, proposed in 1836; the punctures proposed by Anderson, of Baltimore, in 1835; the Cressom operation of 1838; the Belmas operation of gelatine strips in the canal; the modern revival of the suture royal by Czerney, to the last and most prevalent treatment, by continuous compression.

I have before spoken of the early invention of the truss, and you all know that there would not be space in this hall to exhibit the various modifications that have been invented. Hard pads, soft pads, air pads (Jeanney, 1838), springs and no springs, ratchets, catches and binding screws of infinite variety. Although radical cures of inguinal occur in mild cases, it is well known that trusses are in the main merely palliative; that permanent cures are rare, and closely confined to those of recent date with small openings, yet we go on ordering trusses for our patients just as if there were no way to increase the proportion of cures, and as if a truss could not as well be worn after an operation, if need be, as before it, and as if no recent advances in abdominal surgery had been made. As no logical reason can be given for a failure to accept the view that there has been an advance, I perhaps need not say that *I favor in all cases affording even a reasonable prospect of cure, an operation therefor, and that all cases whatsoever of bubonocoele should be operated upon.*

Spontaneous cures of hernia, while uncommon, occasionally happen, and there are several cases on record. The most recent case is that by Dr. Streeter, of Glen's Falls, N. Y., where in consequence of sup-puration in the inguinal canal following a bubo, the canal was closed, and the hernia cured. The patient had previously worn a truss for a year, without avail. But a surgeon would be hardly likely as a general practice to recommend his patients to acquire a bubo.

I conclude by quoting the remark of Sir Spencer Wells, made many years ago:

"But the surgeon who cures hernia radically with certainty and safety, is a greater public benefactor than he who saves the life of his patient in strangulated hernia, as he not only relieves a larger number of his fellow creatures from the suffering and inconvenience of wearing a truss, but he averts the danger of strangulation to which they are continually exposed in a greater or less degree through every period of life."

THE BEST FORM AND PRACTICAL VALUE OF THE SHADOW TEST IN THE MEASUREMENT OF REFRACTION.

BY EDWARD JACKSON, A.M., M.D.,
CHIEF OF THE EYE CLINIC IN THE PHILADELPHIA POLYCLINIC.

The purpose of my paper is to draw attention to the practical value of the shadow test, or retinoscopy;

and to insist on the importance, for its successful and satisfactory employment, of certain conditions which have not received due attention at the hands of other writers upon the subject. In this country most ophthalmologists are not familiar with the test. See Dr. Loring's curt dismissal of it as of no practical importance; while of recent English writers Swanzy gives it eight pages of the seventy-three devoted to the whole subject of physiological optics and ametropia, Juler assigns to it ten, out of seventy given to errors of refraction, Hartridge one-eighth, and Morton one-sixth of the whole of their respective books on refraction.

I can readily understand how an acquaintance with it, based on some of the printed descriptions and a few unsuccessful attempts to apply it, would lead one to think lightly of its value. But no one who has mastered it, has felt, or, I think, will feel inclined to leave it unused; no matter what other methods he may have for the estimation of ametropia.

The principle of the test is simple. From each point of the illuminated retina rays of light pass through the dioptric media into the air. If by the proportions of these media, or a convex lens in front of them, these rays are rendered convergent, they meet in a real focus in front of the eye. If we determine the distance from this focus to the eye we determine the state of refraction in the eye, with or without a convex lens of known strength before it. At this focus the rays cross. Their relations become reversed. When an observer receives in his own eye these emergent retinal rays, if he receive them before they cross, he sees an erect image of the retina; if he receive them after they cross he sees an inverted image of the retina. Placing the eye alternately within and beyond the point at which they are focussed he sees first an erect, then an inverted image. The reversal of the image occurs at the conjugate focus of the retina. I have therefore called this *the point of reversal*.

As the point of reversal is approached from either side, the image of the retina becomes enormously magnified and very indistinct, and just at the point the pupil becomes occupied by a perfectly uniform feeble glare of light. Even some distance from this point the details of the fundus are quite difficult to see. An inspection of these details is not, therefore, a satisfactory method of determining the position of the point of reversal. The best object by which to determine if the retina is seen in the erect or an inverted image is a small area of light moved across it; obtained by throwing into the eye with a mirror the light from some lamp. By turning the mirror the light area is made to move across the retina in any desired direction, and the direction of its motion is readily known, for some of the light falls on the face, forming a light area there, and the areas on the retina and the face always move in the same direction. Now, watching through the pupil the apparent movement of the retinal light area, we can note when this is with the real movement, the retina being seen in the erect image, and when it is the opposite of the real movement, the retina being seen in the inverted image. And this direction of the movement can,

under proper conditions, be recognized close enough to the point of reversal to determine the position of that point with great accuracy.

Now there are two ways of fixing the position of the point of reversal. Either, as above indicated, the observer may move his eye first within, then beyond it, while the point itself remains fixed; or he may keep his eye fixed and move the point of reversal by placing in front of the patient's eye weaker and stronger glasses alternately until he knows just what glass will bring it to a certain position. The latter method has been followed by Cuignet¹ and the mass of those who have practised or written upon retinoscopy. The former was proposed by Chibret² for the determination of myopia; and by myself³ for the determination of ametropia of all forms. It is the better way, because it is easier to vary the observer's distance than to make all the necessary changes of glasses, especially where, as in most cases, it is only desired to approximate the error of refraction to get a basis for subjective testing.

The variation of the distance between the observer and patient requires the use of the plane mirror. The plane mirror can be used for the other form, as described by Story.⁴ But while the plane mirror answers for either, the concave mirror is only serviceable when the position of the observer is fixed, and that of the point of reversal varied. This is because the retinal light area must have a certain brilliancy and minuteness, for its motion to be readily watched. And with the concave mirror, if the observer approach the patient the retinal light area gets too large; if he withdraw from the patient it gets too dim. There is just one point at which the size and brilliancy of the light area are the same with the concave as with the plane mirror; its distance from the patient's eye is found by this proportion: $a-2d:2a::d:b$, in which a is the distance from the source of light to the mirror, d the focal length of the mirror, and b the desired distance from the mirror to the patient's face. Applying this formula, it is found that the greatest distance at which the concave mirror can advantageously be used without a specially brilliant light is but little over four times the focal distance of the mirror; if the light be placed back of the patient's head. For the ordinary concave mirror of 22 centimetres focal length, the proper distance is a little less than one metre. As I have pointed out in the paper above referred to, for accuracy it is best to make the final estimate of refraction with such a glass before the patient's eye as will bring the point of reversal over one and usually less than two metres from the eye. Morton and Barrett⁵ have, apparently without knowledge of my paper, come to the same conclusion. But as they were working with the concave mirror, the common forms were found of too short focus. So they propose a special concave mir-

ror with a focal length of thirty-six centimetres for accurate retinoscopy. Such a mirror could of course be used.

The need of a special form of mirror of course destroys the one advantage that retinoscopy with the concave mirror was supposed to have, namely: that we could practice it with the mirror of the ophthalmoscope already in our pockets. But for most American ophthalmologists that supposed advantage was most illusory. With us the segmental tilting mirror of Dr. Loring is commonly used, and for good reasons. But it is entirely unsuited to retinoscopy because it is too narrow. With it the light area is apt to pass entirely off the eye before the retinal area has moved sufficiently to indicate the direction of its apparent motion. I believe it is on account of the unsuitableness of the mirror used more than from anything else that the profession in this country has failed to avail itself of the shadow test. English and French ophthalmoscopes are almost invariably fitted with a round mirror over an inch in diameter; and even these are being discarded for larger mirrors specially adapted to the purpose. The form of mirror I use, and recommend, is that described in the current volume of the *Medical News*.⁶ It is one and one-half inches in diameter, being quite as small as will, under all ordinary circumstances, prove satisfactory.

One other point as to the best method: the source of light should be small and brilliant. I have elsewhere given reasons for this; small, to get the characteristic appearances of astigmatism which become pronounced in so far as the retinal light area approaches the condition of a single bright point; brilliant, to make the margin of the area and its movements more readily discernable. The best source is unquestionably the arc electric light; but it is not generally available, and any bright lamp flame will answer. In my office I commonly use an argand gas burner, which is covered by a metal chimney with an aperture one inch in diameter opposite the brightest part of the flame. Placing the patient a couple of yards away from the light, I have a source of light small enough and bright enough to answer the purpose. As improving by contrast the brightness of the source of light, the room should be thoroughly darkened for the application of the shadow-test.

The practical value of a diagnostic procedure might be considered with reference to its capacity to reveal that which could be discovered in no other way, with reference to its certainty, its accuracy, and the readiness with which it is put in practice. For the mass of cases undoubtedly we have other ways of determining the refraction. But in a few cases retinoscopy is the only satisfactory and reliable way of doing this. For instance, where the patient cannot be relied on for subjective tests; and the eyes cannot be well fixed for the estimation of the refraction by the erect method, as when there is nystagmus. In several cases of nystagmus the shadow-test has shown me the presence and exact amount of considerable degrees of astigmatism, unsuspected after ex-

aminations with the "refraction ophthalmoscope" and considerable testing with test-lenses. The case which first powerfully impressed me with the value of the test was one of a restless, wilful, spoiled girl of eleven. Where with the ophthalmoscope I could detect the presence of considerable hypermetropic astigmatism, but neither with this or the test-lenses could fix even approximately its amount or axis, her answers for subjective tests were utterly unsatisfactory and unreliable. Finally, in despair, I turned to the shadow-test which I had been studying and using in a rather tentative manner. With it I worked out the refraction and placed the lenses, R.—0.5=+2. cy.ax. 110°. L.+2. cy.ax. 70°; bringing her vision for either eye from $\frac{1}{8}$, the best I had before been able to obtain, to $\frac{1}{4}$ partly. The surprise occasioned by the improvement in vision disarmed her of wilfulness, for the time, and I was able to get full subjective confirmation of the accuracy of the correction. Now, such is my confidence in the certainty of the method, that I would not hesitate in such a case to order the glass though the patient said it made the sight worse instead of better. For certainty an objective method, I think we all agree, is infinitely superior to any subjective test.

For accuracy, retinoscopy is considerably superior to the direct examination with the ophthalmoscope. In hypermetropia, myopia and regular astigmatism, I think the limits of error may be placed as within a half dioptric. To discover irregular astigmatism and its character and extent, it is far superior to any other method of examination, as most of you doubtless know by experience; for it was applied for this purpose by Bowman and Donders long before Cuignet's description of "keratoscopy" was written. Loring says: "The determination of astigmatism by means of the ophthalmoscope has always been considered one of the most difficult and, from its want of accuracy, one of the least satisfactory applications of the instrument, and there is no doubt that this is to a great extent true." Here is the special field of retinoscopy. While Loring says of his method: "0.75D can be detected by this test, provided the accommodation in both the observed and observing eye is perfectly relaxed," it may be said of retinoscopy that under similar conditions of the observed eye, it will measure 0.25D of astigmatism, while the observer's eye may be entirely unskilled in the art of relaxing the accommodation; and with full power of accommodation in the observed eye 0.5D of astigmatism is readily detected.

The description of the method indicates the readiness with which it may be practiced. In simplicity of apparatus it stands alone. And I need scarcely tell you that in the fixing of astigmatism it saves time as well as gives certainty.

Let me close with this caution: the possibilities of practical value in the shadow test only appear when the details I have mentioned are carefully attended to. It is not to be acquired by the reading of a description, and a few desultory trials, nor will a single successful determination insure that all others will be equally certain and exact. In this, as in anything else, accuracy is only attainable by care and skill.

A CASE OF ULCERATIVE ENDOCARDITIS.¹

BY GRACE WOLCOTT, M.D.,

OF BOSTON.

On the 17th of October, 1884, I was called to see Mrs. R. M., 40 years of age. She had been a tailoress until her marriage, six years before. She told me that three years previous to this visit she had rheumatism, for which she was treated about one year. She fancied that the remedies given her then, increased the menstrual flow very much at first, and finally arrested it altogether. This so alarmed her that she refused to take any more medicine, and had had no further treatment up to the time that I saw her, although she had suffered greatly with her heart in the meantime. She was a slender woman, rather over medium height. Her face was very pale, her lips bluish, cheeks sunken. She seemed very nervous and her voice was tremulous.

Her pulse was 108, very irregular in volume and rhythm, and frequently intermitted. The radial pulse was so weak that I could not count it accurately, and from this time I was obliged to take the pulse over the heart's apex. Temperature and respiration were normal. The bowels were constipated. The tongue was furred and the breath foul. She complained of gaseous dyspepsia, and of pain over the apex, accompanied by dyspnoea and palpitation, after any physical exertion or mental excitement.

Physical examination showed the apex beat to be in the fifth interspace, three and one-half inches from mid-sternum, and the area of cardiac dulness to be somewhat increased. At this examination the heart's pulsations were so weak and irregular that no diagnosis of the valvular condition was made.

The treatment was directed to the heart itself and the sluggish condition of the bowels, as I thought the dyspepsia was secondary. The bowels were unloaded by a simple laxative, and under the influence of the tincture of digitalis the number of pulsations was reduced from 108 to 80 per minute, the beat becoming stronger and more regular. Auscultation then revealed a double mitral and a double aortic murmur. The dose of digitalis was then reduced from gtt. x to gtt. iii, three times daily, and she was given a pill of cinchona, iron and gentian, and under this treatment she gradually improved. Two weeks from my first visit her pulse was 74 per minute and regular, the bowels moved daily and she was able to go up and down stairs and to take long walks without discomfort.

She continued in this condition until November 26, when after severe nervous excitement, she came to my office suffering from palpitation, dyspnoea and dyspepsia, with a pulse which varied from 116 to 128 beats per minute. Digitalis was again administered and soon all trouble subsided.

On January 12, 1885, I was again called to see her. She had taken a severe cold and had rheumatic pains with constipation, headache, anorexia and vomiting. The pulse was 120, the apex beat very feeble. Her face was extremely pale. She was put to bed

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, May 12, 1886.

and the tincture of digitalis was again given in gtt. x doses, and treatment suitable to her febrile condition was instituted.

January 13. The pulse rate was reduced to 72 per minute, but she suffered greatly from nausea, and passed a sleepless night.

January 14. She complained of severe pain over the præcordia. Urinescent; specific gravity 10.20; one-fifth albumen by bulk and loaded with urates. A flaxseed poultice was placed over the region of the heart and potass. bitart was administered in small doses every two hours. Sulphate of quinine was given thrice daily and sulphate of morphia at bedtime.

January 15, A.M. The temperature was 101.8°, pulse 76 and respirations 36. The pain over the præcordia was very much lessened but the patient complained of severe pain in the right and left lumbar regions. At this time coarse moist râles were present in both lungs, accompanied by a cough with profuse expectoration of mucus.

January 16. She was rather better and from that date she gained slowly, the convalescence being interrupted only on January 22 and 23, when she had chills followed by sweating. No unfavorable symptoms followed, however, and she was soon able to sit up and her appetite returned. She was given a pill of quinine, arsenious acid and gentian, and the digitalis was continued. She expressed herself repeatedly as feeling better than she had felt for more than two years. She was able to go over the stairs and to walk down town and back. I tried to impress upon her many times the necessity for continuing the digitalis, but she felt so well that she did not see the need of it, and soon after I stopped my visits she stopped all medication.

She had similar attacks on March 7, 15 and 30. The pulse on each of these occasions was 140 but was quickly reduced by digitalis or caffeine. The period from April 4 to April 19 was one of great comfort. She was able to walk long distances every fine day, and to do her housework with perfect ease. At this time I considered all her discomfort to be due to the fact that the limit of compensatory hypertrophy had been reached and dilatation had begun, the crippled condition of the aortic and mitral valves having probably originated in the attack of rheumatism three years before.

With the exception of a slight pericarditis in January the patient had with each attack, bronchorrhœa, dyspnœa and various gastro-intestinal disturbances, all of which disappeared as soon as the heart's action was fully under control, and invariably reappeared about one week after she stopped medication. Repeated microscopic examination of the urine revealed nothing abnormal.

On the morning of April 20, I was called to see Mrs. M., and was told that the previous evening just after going to bed, she had a violent chill, that the chill was followed by profuse sweating, severe pain in the right lumbar region, and that she had passed a restless and sleepless night. At this time, about 8 o'clock A.M., the temperature was 101°, pulse 140 and irregular, respiration 40. Her face was very haggard and anxious. Orthopnœa was marked and

there was a copious expectoration of glairy mucus. The prostration was so extreme that the physical examination was necessarily hurried and superficial, but I found on percussion that there was flatness over the lower part of the right chest and on auscultation mucus and subcrepitant râles over both lungs. Her stomach was very irritable and it was with difficulty that she retained any food. She was given one of the ammonia salts together with quinine and morphia.

April 21, there was an improvement and her temperature had reached 103°. I then asked Dr. A. N. Blodgett to see her with me in consultation. A careful examination revealed a slight effusion in the right pleural cavity, œdema of both lungs, and pericarditis friction sounds being present. The possibility of the existence of ulcerative endocarditis was suggested by Dr. Blodgett. No change in treatment was advised, except with regard to stimulants and milk. These had been tried repeatedly, in various forms, but unsuccessfully; however, we renewed our efforts, but to no purpose.

During the 22d and 23d, she remained in about the same condition except that she grew gradually weaker. On the night of the 23d, she went into a comatose state which lasted until 9 P.M., of April 24, when she died.

During the illness, which lasted five days, the temperature ranged from 101.5° to 103° there being marked morning remissions and evening exacerbations. The pulse was 140 throughout the attack and the respirations 40 to 48 per minute. Orthopnœa was present from the first, but she complained of no discomfort or pain about the heart at any time. The profuse expectoration was very annoying to her as she could only raise it with great difficulty on account of the prostration. The skin was cold and clammy to the feel, and sallow, almost cadaveric in appearance. Permission to make an autopsy was given at so late an hour, and the time allowed for it so limited, that great haste was required. For this reason the chest only was opened.

Autopsy. Made twelve hours after death. Body fairly well nourished. Rigor mortis present. The lower half of right lung firmly bound to costal pleura by old adhesions; a few recent adhesions were found. The left lung was entirely free. The right pleural cavity contained about a pint of fluid. The left chest was normal. Slight hypostatic congestion over posterior part of lower lobes of both lungs, and both were œdematous.

The pericardial sac contained about 3ij of fluid. The heart was increased fully one quarter in size. Its walls were hypertrophied and its cavities considerably dilated. On the outer surface of the heart, along the course of the left coronary artery were evidence of inflammation in the shape of little bead-like deposits which were quite firm. Near the apex on the outer surface of the left ventricle was a patch of inflammatory exudation about the size of a small lima bean, which was quite soft. There were several similar patches, though much smaller, at different points of the visceral pericardium, also some cloudiness.

In both articles and in both ventricles were large

ante-mortem clots, the clot in the left ventricle extending into the aorta. The endocardium of the left ventricle showed evidences of recent inflammatory action in the shape of cloudy patches and delicate shreds of plastic matter.

The leaflets of the mitral valve showed fibroid induration, the orifice admitting but two fingers. The ventricular surface of the cusps of the aortic valve were the seat of the ulcerative process. In opening the aortic orifice, the incision was made at the junction of the right and left leaflets next the pulmonary artery, dividing one ulcer, the largest one, which measured three-eighths of an inch by one-fourth. It was of a dirty grayish color, and beneath was disintegrated tissue.

The second ulcer was at the junction of the posterior and right cusps.

A little to the left of the middle of the right cusp was a firm mass about the size and shape of a small pea, with beginning ulceration at its apex.

On the posterior cusp were two similar nodules, one of which was slightly softened at the apex, and the other firm.

There were also evidences of inflammation of the aorta extending about an inch and a half from the aortic orifice.

I am glad to lay before the Section the report of this case, with the specimen, for the criticism of its members. It seems to me that the specimen presents *well*, a gradation of the process from the indurated nodule to the open ulcer.

MEDICAL PROGRESS.

BOILED AND UNBOILED MILK.—The inability, or the disinclination, of the modern woman to supply to her young its natural pabulum, is the most fruitful cause of the high per centage of mortality in infants under two years of age. The ingenuity of man has united with his knowledge of physiology and chemistry to supply a substitute for the natural secretion, and we have in the market a large variety of artificial foods for infants. While some of these are tolerably successful, few, if any, are equal to the milk of the cow, which, with slight modification, and with proper care in its preservation, may be made to quite closely conform to human milk. In spite, however, of the most scrupulous care, raw milk is frequently found to be illy borne. Recent experiments by DR. REICHMANN (*Deutsche Med. Zeitung*) seem to show that by boiling the milk these difficulties may be obviated. The following are the formulated results of these experiments:

1. Boiled milk leaves the healthy stomach more rapidly than an equal quantity of unboiled milk.

2. The digestion of boiled milk is more rapidly accomplished than that of unboiled milk.

3. The coagulation of unboiled milk in the stomach is complete in five minutes.

4. The coagulation is not caused by the acid of the gastric juice, but by the influence of a special ferment (milk-curdling ferment).

5. The acidity of the gastric juice is at first due almost solely to lactic acid, and, later in the process of digestion, to the presence of hydrochloric acid.

6. Hydrochloric acid first appears in perceptible amount forty-five minutes after the ingestion of half a pint of milk.

7. For the first hour and a quarter after the ingestion of milk the acidity gradually increases and then decreases until the milk has entirely left the stomach.

8. The curds of casein, in digestion of boiled milk, are much softer than in the case of uncooked milk.—*Medical Age*, August 10, 1886.

CONNECTION BETWEEN SPLENIC TUMOR AND THE UTERINE FUNCTIONS.—DR. SKORCZEWSKI describes in the *Przegląd Lekarski*, a Polish medical journal, a peculiar case of splenic tumor which had a distinct relation to the generative organs. A woman aged 26, after a difficult labor four years ago, experienced pain in the left hypochondrium, and in the course of a few days noticed a tumor in the abdomen, which rapidly attained to the size it was when first seen by Dr. Skorczewski. It then occupied nearly the whole abdomen, being of an ovoid form, the long axis being transverse. It was hard, with smooth thick edges, and could be displaced upwards to the extent of a hand's-breadth above the symphysis pubis. The urine was normal; also the number of blood-corpuscles. Quinine and arsenic produced no effect. Electricity was then tried, and after a course of the interrupted followed by another of the constant current, occupying together some three weeks, the tumor had diminished so much that when pushed up under the left ribs it only extended about a hand's-breadth below them. The patient's general condition, too, had become decidedly better. Menstruation, lasting four days, then occurred, and simultaneously the tumor again increased to its original dimensions, and the woman's general condition became worse. Neither electricity nor other methods of treatment which were tried produced any fresh diminution in the tumor or any improvement in the general condition. The connection between the splenic tumor and the functions of the generative organs were evident enough, but no explanation of this connection seems to have suggested itself to the author.—*Lancet*, May 15, 1886.

ANACHARIS ALSINASTRUM.—DR. BRANDES has recently declared the valuable properties of the anacharis alsinastrum, a water-plant which has hitherto been considered as a nuisance. He says that in the district where he lives, and where malaria and diarrhoea yearly appeared in a sporadic or epidemic form, those diseases have gradually decreased since the anacharis alsinastrum began to infest the neighboring rivers and marshes, and for four years have totally disappeared. He proposes that the plant, which came originally from Canada, should be planted in marshy districts, with the view of checking malaria; and the experiment, in view of the evidence adduced in the article under notice, is certainly deserving of consideration.—*Medical News*, August 28, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

CHICAGO, ILLINOIS.

SATURDAY, SEPTEMBER 4, 1886.

"THE HIGHER EDUCATION OF WOMEN."

Is it for the good of the human race, considered as progressive, that women should be trained and admitted to compete with men in the ways and walks of life from which, heretofore (as unsuited to their sex), they have been excluded by feeling and usage, and largely, indeed, by actual legislation? Such is the question discussed by Dr. Withers Moore in his Presidential Address before the fifty-fourth annual meeting of the British Medical Association. The Address was timely, and the subject one which it was proper that the President of a great Association should discuss; for if the proper answer to the question be the negative, and negative for reasons of public health, it was proper that the dangers should be pointed out by a medical man. Is it for the public good that we should have female doctors, lawyers, divines, professors, Ministers of State, astronomers, mathematicians, generals? Were women intended for work of this kind by nature? Is such work of special detriment to them as well as to the public good?

"The first requisite to success in life," says Mr. Herbert Spencer, "is to be a good animal; and to be a nation of good animals is the first condition to national prosperity." To be a race of good animals is also, as Dr. Moore points out, the first essential of human well-being. To be a good animal means a great deal. We often hear it said that we do not so much want a very robust health as great intellectual attainment and intellectual strength; that it is the mind, the brain of a nation which makes it; and that in the struggle of life the body must take its chance, but come what may the mind must be pushed to the

utmost. It would of course be a waste of time to argue such a question before intelligent and thinking medical men. The question which Dr. Moore has asked and discussed is one that has a peculiar interest for the American. We are a people in a hurry, and we take but too little interest in what our neighbor is doing so he does not interfere with us. Many of our aims and ends are attained at an expense of nerve and muscle force which is unknown to other nations. But that is not because we are deficient in brain-force; it is because we do not pay sufficient attention to the proper development of the body that must sustain the brain. Our breed of men must be bettered, and the first requisite to this end is to have the breed of women bettered; good male animals cannot be reared without good female animals. Law and custom have, from time immemorial, imposed certain restraints upon women; are we thoughtlessly to throw aside these restraints and place women in competition with men? When we ask the question, Is the preliminary training for such competitive work, and the subsequent practice of it in the struggle for existence, of such a nature that it will more or less indispose and incapacitate women for their proper sphere, their proper function, of being mothers of men? we must look for the answer from those who can give a practical answer—no theoretical or sentimental people can give a correct answer.

One of the best answers to these questions may be found in the first chapter of Emmet's work on "Gynæcology," pages 17 to 25. It is a chapter which should be reprinted and placed in every family and school in the land. One effect of this higher education of women, of which we hear and read so much, will be to hinder those who should be good mothers of men from being mothers at all. Good, the best, women cannot take the place of good men; they may do some of the work that would have been done by the sons, but they cannot do *the* work that the sons would have done under any system of training. A good professional education is very expensive; the expenditure is not alone one of money, but there is an enormous outlay of physiological force; much more than a woman can afford, if she is to perform her proper functions as a producer of men. Clearly that is the function of woman, for she is the only means by which man can be brought into the world. The production of children calls for far more physiological force on the part of the mother than of the father. The functions of gestation and maternity require a great outlay of physiological force, and if this force is used up in other work the offspring of the world must suffer, as must the woman herself.

We have, then, two channels of expenditure of physiological force of the woman: the terrible strain of higher and professional education, the training for competition with men in the most severe exercises of the intellect, and the expense of being properly trained for motherhood. It is of the greatest importance to a man, to his country, that he should have had a good, an able mother, a strong mother; a healthy, strong animal, as well as an intellectually strong human being. More than being mothers of men, women are the mothers of mothers of men, of the material of which men are made. "Material," says Dr. Moore; "why the word itself is but the Latin of mothering, a lengthened out form of *mater*. We have no corresponding *paterial*." Not only is woman the producer of this man-material, but she has charge of its shaping and moulding during the most plastic period of its existence. But "instead of nine or ten years forward, from his beginning on the day on which he was born, go nine months backwards, to the true beginning and starting-point of him, when, by growth and development, he had to be built up and prepared for being born. The whole ante natal structure, with all its complexities, is merely and exclusively made out of the mother's living substance; it has been subjected to influences and impressions exclusively maternal; it is mother-stuff throughout. And this goes on thus all the time during which it is developing into readiness to become the new-born babe—the man that is to be. Blood and bone, nerve and muscle, are all made out of mother-stuff. Can we exaggerate the importance to the future man of the quality of the mother-stuff? And is it not equally important to the future woman, the future mother?

"Educate a woman, and you educate a race." This saying is full of promise if it be rightly interpreted; full of dire disaster if it be applied to the mind to the exclusion of the body. While it may be true that too much bodily labor may render women less prolific it is very much more clearly shown that excessive mental labor is a cause of sterility (or infertility). "In its full sense," says Herbert Spencer, the reproductive power means the power to bear a well-developed infant, and to supply that infant with the natural food for the natural period. Most of the flat-chested girls who survive their high-pressure education are unable to do this. Were their fertility measured by the number of children they could rear without artificial aid, they would prove unable to do this." It would be a curious and a not uninteresting task to take a census of the nursing bottles used in the various civilized countries. It would be a toler-

ably accurate index of the animal-power of the women in those countries. It is extremely probable that twice as many are in use in America as in any two or three countries of Europe; and when we come to compare this country with China, for example, it is safe to say that we destroy more nursing bottles each year than have been used in China since the instrument was thought of. Our education, our civilization, is one that stunts, deforms and enfeebles women; and as such it must be unsound. Shall we make it worse by placing women in competition with man, by still further stunting, deforming and enfeebling her animal powers? The goal to which we are going is to have the weaker and inferior woman perpetuate the race; the very ones who, if any, should be prohibited from producing men and mothers of men. If it were at all necessary in the interests of human progress, if it were likely that the world and mankind would be the better for it, there would be an excuse for a thorough and honest trial of it; but there is neither necessity nor justification. And this is more applicable just in proportion as the women under consideration have had unfavorable antecedents as to food, rearing, and general surroundings. At best they are scarcely fit for reproduction until the animal has been more fully developed; this not done, and the immaterial animal is developed to the disadvantage of animal powers, and they are fit for nothing. Instead of development there is degeneration and impaired nutrition, and evolution gives way to nervous and bodily dissolution.

Whatever does, or tends to, render women infertile is prejudicial to a nation. The sterility of its women caused the downfall of the Roman Empire, or was one of the principal causes; among modern peoples the French are giving the world an example of decadence which is largely due to infertility of its women. Every woman cannot be a mother, or a wife; no more can every child grow to adolescence. But it is not assuming too much to say that woman was born to marry and bear children. In England, for example, there is an excess of marriageable men. This is to be attributed to England's standing army; the husbands of those unmarried women may be found scattered and buried all over the earth. To say that if every woman was a wife it would involve many unions worse than solitude is entirely outside of the question which we are discussing; that people will contract foolish marriages is no argument against the principle of marriage. We cannot agree with our contemporary, the *British Medical Journal*, in its Hibernianism that "if every English woman were employed as a wife, there would still be a consider-

able surplus who would have to employ themselves." There are some women who must work, and if they cannot find woman's work to do then they must work as best they can, even if as men. But there is now a tendency to turn a woman into a man as a sort of experiment or *fad*; a young girl, unthinkingly perhaps, takes it into her head that she must do man's work, though there is no necessity for it, and when she has not the constitution to do a woman's proper work. Parents, teachers, and the family doctor should endeavor to repress this growing tendency. If our girls were more properly taught at school, if they were taught the true physiology of woman, of life itself, this tendency would be in a great measure stopped. We cannot turn man into a woman, nor fit him to perform a woman's duties; no more can we fit woman to perform the work and duties of a man.

THE REMOTE EFFECTS OF REMEDIES.

The Addresses in the Sections of the British Medical Association this year were of an unusually brilliant character, and without invidious comparison it may be said that none were more interesting than that in the "Section of Medicine," on "The Remote Effects of Remedies," by DR. W. H. BROADBENT. As it is necessary to have in view in the treatment of disease the remote effects of the disease, so we should look beyond the immediate effects of the treatment, of the remedies used, to the remote effects. If we give morphine or bromides to-day what will be the effect to-morrow or the next day? If we use them all this week what will be the effect next week or next month? Will not the remote effects be different on different persons, and wherein will they differ? We may use alcohol, for example, with safety as regards future effects in one case, but in another these effects will far outweigh the possible benefits. We may administer chloral for the purpose of inducing sleep, but should the patient depend on the drug instead of taking the proper exercise, and get a proper amount of fresh air, the remote effects of the drug will be as bad or worse than a temporary insomnia. Equally bad are the remote effects of cocaine when a person of weak will once finds that its use will bring activity, exhilaration, and excitement. It may be said that the injurious effects which follow the continued use of a drug are the result of the patients taking the remedies into their own hands, of abuse rather than use; and this whether the patient has at first undertaken to treat his own case, or whether the drug has been first prescribed by a physician, or its use sanctioned by

him. Of course there are some cases in which the remote effects cannot be clearly seen; but it is well to be on our guard.

In treating a case of gout, for example, we can cut short the attack by the free administration of colchicum, veratria and other drugs of similar action. The injudicious use of the drugs may cause immediate prostration, and the remote effects may be very disastrous. But the violent pain of acute gout warrants us in using colchicum, but on the condition that proper precautions are used to prevent the remote effects; we institute an after-treatment with aperients, alkalies, iodides, and careful regulation of the diet. The after-treatment, especially the strict diet, is unpleasant to the gouty patient, and is frequently disregarded. It is difficult to make him see that the after-treatment will do what the attack of gout would have done—clear the system of the gouty poison, and bring the secretory and excretory organs into a state of functional activity. On the assumption that gout is due to the formation of uric acid in the system, it is not supposed that the use of colchicum will arrest this formation, it only checks antecedent metabolism, and then nitrogenous waste rather than urea and uric acid accumulates in the system. They provoke resistance in the arterial tree, and then comes increased arterial tension, with all its dangerous consequences. All the consequences of increased arterial tension—vascular and cardiac troubles, arterial degeneration, cerebral hæmorrhage, aneurism, cardiac dilatation, and valvular disease—may be prematurely induced by means taken to keep down or prevent an attack of gout. This is very readily seen in workers in lead, which, as we know, is a common cause of gout when accumulated in the system. Painters and plumbers take all kinds of gout specifics, the attacks are suppressed or prevented, the system becomes charged with imperfectly oxidized matter, and we see as a result deposits of urate of soda in the small joints, the arteries injured by degenerative changes, due to high pressure; or the heart may be dilated by resistance in the peripheral circulation; granular disease of the kidneys comes on, as a result of the state of the blood, or of the vascular tension to which the state of the blood has given rise; the renal lesion often aggravating the bad state of the blood. In this state the system is easily overcome by diseases which under other circumstances it would safely weather. The "Banting" system of treating obesity may also cause high arterial tension. The highly nitrogenized diet, the exclusion of non-nitrogenous substances, and the limitation of the amount of fluid taken, gives a disproportionate amount of nitrogenized matter in the

system, while there is not the amount of water necessary for active metabolism and elimination. A part of the system is a large amount of exercise, and it is a very necessary part, but it is the very part which is most frequently neglected.

In some of these cases it is the patient himself who is wholly responsible for the consequences, interfering ignorantly with natural processes, but medical men are sometimes responsible for very similar errors. Dr. Broadbent thinks that "a similar error, for which medical teaching is directly responsible, is committed when strict dietetic treatment is insisted upon in the glycosuria of stout elderly gouty subjects. I will not stop to discuss the question whether this is to be called diabetes or not; but to be quite clear, I may state that the cases I have in mind are not those in which there is merely, from time to time, a small amount of sugar in the urine, but such as have copious urine with high specific gravity, and the constant presence of much sugar, often with thirst. Now, in some of these patients the establishment of habitual and free elimination of sugar is coincident with the disappearance of many distressing symptoms, especially digestive troubles, loss of appetite, irritability of temper, disturbed sleep, and morning depression. "The altered chemistry of the liver is, in some way, a relief; perhaps it is by the increased elimination of the urea which accompanies the sugar, the two coming from the splitting up of nitrogenized matters. I do not wish to argue from this, that we must let the glycosuria alone, but only that we must bear it in mind in our treatment. Now, in my experience, this form of glycosuria is almost always associated with high tension in the pulse, which is not constantly the case in the diabetes of early life, the pressure in the arteries here being often extremely low; as everyone knows also, it is common in gouty persons, and it may or may not appear to relieve the gout; very often it does nothing of the kind. It appears to me that, with all these evidences of the presence of nitrogenized waste in the blood, it can scarcely be right to insist on a diet from which non-nitrogenized matters are strictly excluded. It may be added that, as a matter of practical observation, such a diet is rarely, if ever, adhered to; patients belonging to this class are not usually such as have been accustomed to self-restraint, or such as can resist the solicitations of a newly reviving appetite; and, when it is attempted, do we not find the mouth to become foul and dry, the appetite fail, the bowels deranged, till we are compelled to relax the restrictions?" In some of these cases the heart suffers, or has already sustained some injury, and the long full pulse

of sustained tension has given way to the short sudden wave in a large full artery—a sign of dilatation which examination of the heart will confirm. These are the cases which are so much benefited by the eliminant action of large quantities of water, particularly when certain saline matters are found in the water. There is direct proof that elimination is the therapeutic indication. The health of the patient is what we are after in these cases, more than the removal of all the sugar from the urine. Under an eliminant treatment the patients feel and are better, with a modified mixed diet, than on what is called a strict diabetic diet. And more than this, under the eliminating action of a blue and colocynth pill, once or twice a week, followed by salicylates and alkalies, the sugar often disappears from the urine for months and years.

The continued use of the solanaceous drugs for asthma, especially in cases of catarrhal asthma, and of certain "asthma cures," while at first bringing relief to the suffocating patient, will in time produce such effects on the vascular and nervous systems, stupified mental condition, congested face and eyes, the large sluggish pulse of arterial paralysis, dilatation of the right heart, that they must be discontinued or they themselves will kill the patient. Probably no one affection is so persistently maltreated as sick-headache; and almost on a par with this may be placed the so-called indigestion. There are very many cases of each, or both combined, which call for eliminant and tonic treatment, but which do not get it. In indigestion it is often the case that the stomach must be immediately built up to the food, instead of putting the food down to the low level of the stomach. In the first it is often imperative to build up the blood and nervous system, the heart itself, so as to keep up a state of constant elimination of effete matter. "It is quite true that most people eat far too much, and, again, that with regard to the stomach, as well as to all other organs and parts of the body, the principal of functional rest is of primary importance in dealing with disease; and restriction of food, and even temporary starvation is often necessary; but we must distinguish, and not starve, those who are suffering from inadequate nourishment, or employ treatment for catarrh, or ulcer, or organic disease, when nothing of the kind is present."

THE INGLESBY LECTURES.—On September 2d and 3d Mr. LAWSON TAIT, President of the British Gynaecological Association, delivered two lectures on "Recent Advances in Abdominal Surgery," in the Queen's College, Birmingham.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, August 16, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. F. E. WAXHAM presented a

MEMBRANOUS CAST OF THE TRACHEA AND LARYNX.

The specimen presented was removed from a child nine years old. This cast had remained in the larynx and trachea for several months. The patient was brought to me from Minnesota by Dr. McDavitt, of Winona. The history is as follows: The child claims that in April she swallowed a hedge thorn while away from home. She was at once taken with suffocation, and twenty-four hours afterwards was operated upon when at the point of death, by Dr. McDavitt, who performed tracheotomy. The child was unable to breathe through the natural passages after the introduction of the tracheotomy tube, although many attempts were made to remove it. It seemed impossible for the child to get a breath through the natural passages when she was brought to me. Upon laryngoscopic examination the larynx seemed to be closed, but digital examination revealed a very small opening into the larynx. In this opening a small sound was passed and this was followed by one of the smallest size intubation tubes, this by a larger one, and finally the largest size tube was introduced. It could not be passed on account of the tracheotomy tube, and violent vomiting ensuing the tube and this cast were ejected. After the rejection of this membrane a large sized tube was introduced and pressed down into position, as the tracheotomy tube was removed, which gave the child perfect comfort. She remained comfortable after the introduction of the tube, took several glasses of milk during the afternoon, and in the evening was taken to the train and returned to Minnesota, the intubation tube remaining in the larynx to be removed by the doctor in the course of a few days.

DR. JOHN B. HAMILTON, of Washington D. C., read a paper on

THE RADICAL CURE OF INGUINAL HERNIA,

(See page 256.)

DR. D. W. GRAHAM said: I think I express the sentiments of every member present when I say that it is probably not possible to find in the English language as complete and satisfactory a review of the history of the various operations for the radical cure of hernia as Dr. Hamilton has given us in this paper. Certainly it has been gratifying and instructive to us all to listen to it. Some of the figures which the Doctor quotes give us an idea of the great prevalence of hernia. I believe reliable statistics show that on an average about every fifteenth or sixteenth individual in civilized communities suffers from some form of it. When we remember this great prevalence, and when we remember that every subject of a hernia sustains thereby a certain amount of disability, and that very many are entirely disabled by it,

the subject of the radical cure of hernia assumes an importance not always accorded to it. I think the author of the paper takes rather a highly colored view of the future of these operations. It is not probable that this generation, at least, will be able to use the expressions he thinks surgeons will be using some day in Chicago. However, this degree of success is to be looked forward to and attained if possible. In regard to the modern methods of operating, I understand the distinctive features of Wood's method to be that it is almost entirely subcutaneous, that he uses wire, and that he allows the sac to remain in the canal as a kind of plug. So far as I know, this method is not practiced in this part of the country to any extent. In Mr. Wood's hands it seems to be successful in permanently curing a considerable majority of those operated upon, and in decidedly benefiting a good many who are not permanently cured. His statistics show that there is almost no danger to life from the operation itself, at least in his hands. Any method which will give such results and at the same time involves so little risk to life, must be a good operation.

The open method, the one chiefly practiced in this country, according to my observation, contemplates strict attention to antiseptic details and the avoidance of suppuration. It involves a little more risk to life from the operation *per se*, but to compensate for this it would seem to give, theoretically any way, a larger per centage of permanent and complete cures. The modifications or varieties consist chiefly in dealing with the sac. Although MacCormac claims that unless the rings are wide there is no advantage in attempting to close them. It seems to me the best way to treat the sac is to excise a section of the neck between two ligatures, pushing the stump into the abdominal cavity and allowing the body of the sac to remain, unless it is small and loosely adherent, when it may be extirpated. After any of these operations there remains the funnel-like depression on the inner surface of the abdominal wall, which favors a recurrence of the hernia however efficiently we may have obliterated the sac and closed the rings. MacEwen, of Glasgow, in a recent article describes and advocates a plan he has devised for obliterating the depression. He utilizes the sac by dissecting it from its surrounding attachments, putting a suture through it from side to side beginning at the lower end, thus making a corrugated pad, which he pushes through the internal ring into the cavity, after first separating the peritoneum for a little distance around the ring with the finger. This makes a convexity on the inner surface of the abdominal wall, when there would otherwise be a concavity. This modification appears to be a real improvement, but the practical value of it is as yet largely conjectural. By way of adding something from an historical standpoint, I might mention, what I think was not alluded to in the paper, that electrolysis has been used and advised to set up a plastic inflammation in the inguinal tract. I believe this suggestion comes from a Cleveland surgeon, whose name I have forgotten. This is the same in principle, of course, as the use of subcutaneous injections, and I should think

would be preferable to the injections, if I were to judge of it without having tried it.

DR. MOSES GUNN said: This subject is of intense interest, and we are very much indebted to Dr. Hamilton for the exhaustive review he has given us. We have to consider what are the best methods for operating with the intent of effecting a radical cure. I am inclined to discard all the old invaginating processes. In the first place, the invaginated portions are always liable to subsequent prolapse; in the next place, it is always a foul mess. It won't do to simply remove the cuticle; all the organs of the skin must be destroyed. The skin contains the hair, sweat and sebaceous follicles, and unless they are destroyed, they will continue their work, and thus accumulate material for decomposition. In order to make a success, you are obliged to do more than destroy the cuticle. You will have to destroy the skin, and that is a very slow process and exceedingly nasty. Therefore I am inclined to repudiate all invaginating processes. I repudiate, also, all of the subcutaneous processes, for they are blind procedures, and I would not adopt them where an open operation could be as well, and even more advantageously and safely resorted to. I believe the best and surest method of trying to effect a radical cure of hernia is the open method. This method should be performed in every case where an operation is made for the relief of a strangulated inguinal hernia. Just as soon as the operator has opened the neck of the sac and restored the prolapsed viscera or viscus, he should close up the wound. He should begin at the topmost portion of the sac, and with a curved needle and catgut take it up and ligate it as near to the internal ring as he can. Then he should drop down about half an inch lower and ligate again, and so on down through the canal. He should then approximate the pillars at and above the external ring as closely as possible and close the outside tissues. Thus the operation which is made for the relief of the accident should be made an operation for radical cure. It can be done more effectively at that time than any other.

Then again, the physician is called upon to make an operation for a radical cure; the patient comes to him complaining of the truss, which has become ineffectual, the hernia escaping in spite of it, and his life becoming a misery to him, and he asks if something cannot be done to make a radical cure. The answer is, "yes;" but the question is, by what method shall we make it? I say by an open operation, practiced with all antiseptic precautions. Cut down upon the parts, separate and dissect out as well as you can the neck of the sac, the hernia having been reduced; ligate the sac and cut out a portion. Thrust the stump back into the canal and approximate the pillars, closing them tightly and keeping the external ring tightly closed. So much for the method; now for the prospect of success. How much right have we to expect what might justly be called a radical cure? By the term radical, I mean permanent. In what proportion of cases can we expect to have a permanent cure, so that the patient will never have hernia again? What is hernia, and who have it? I think I can safely say that the typical man never has

hernia. When the true type in development has been attained and the abdominal walls closely woven together, they are proof against such accidents and there will be no hernia. Hernia is the result of the imperfect development of the abdominal muscles and aponeuroses. When that imperfect anatomical development obtains in the patient, the abdominal muscles are thin and flabby, and in such cases we get hernia. Nor can we in such a case by an operation make a man better than his Creator made him, but if we can make him as good as he was we may congratulate ourselves. After we have operated and closed up this weak point as well as possible, the very best result that we can expect is that we have made the man as good as he was before he had hernia; but, if he was weak enough to have hernia from certain exciting causes, he will be weak enough to have it under similar circumstances again. If his hernia is brought on by lifting and straining, the same exciting cause will bring it on again, and under these circumstances a radical cure is only measurably radical. We should tell the patient after operation that if he will be more careful and take no violent exercise, he may hope for exemption from hernia.

In other cases, the patient has an old and immense hernia and cannot wear a truss; we operate upon him and can say to him that if he will be more careful and wear a truss, he can be tolerably comfortable for the rest of his life. Such, I apprehend, is the true aim and scope of operations for the radical cure of hernia; such are the precautions we should give our patients, as they must become our coöperators in order to make this operation a success; and with such coöperation and conscientious efforts on our own part, radical cure of hernia becomes a standard and important operation, as important as the subject itself, which, as we have seen, is of immense importance on account of the great dissemination of the disease.

DR. E. F. WELLS said: Dr. Hamilton has certainly read a very interesting and extensive paper. There is one point in particular mentioned by the author, namely: that he advocates an operation in all suitable cases where an operation is not distinctly indicated. Every practitioner of large experience must certainly have met with many cases in which the truss has been applied resulting in a cure, and I think the truss should not be stricken entirely from the radical cure of hernia.

DR. HAMILTON in closing the discussion said: I need not say that I am extremely gratified to find such substantial unanimity of sentiment as to the propriety of operation—nay, as to the necessity of operation, but there can be no doubt as to the necessity of further statistics on the subject. In regard to invagination, I think a reading of the paper will not show that I advocated the method of invagination recommended by Gerdy. In the recent open method there is no invagination. Under the original Wood's method, the subcutaneous fascia only was pushed up under the ring; by the open method we cut down directly on the sac. This open method is really a combination method, because it brings together the pillars and takes care of the sac. Statis-

tics are necessarily unreliable as to the ultimate permanency of the cure of these cases. The best statistics are those shown by the Swedish Hospital, where out of 300 cases a large percentage of recoveries is shown, and if statistics are worth anything in determining the success of a method, we must place some reliance on these. It would be well to have patients come back every year for the purpose of re-examination.

Dr. Fenger, if I correctly understood him, speaks of the influence of suppuration in curing these wounds by letting them heal from the bottom, but in the various subcutaneous operations that is exactly what it is intended to avoid. There is no doubt that suppuration will make a radical cure of hernia if the patient's strength lasts, and the suppuration does not extend into the abdominal fascia. That was the method by which the old red-hot irons accomplished their purpose. The mineral acids produced a radical cure by the destruction of the tissue and healing from the bottom. The seton also performed a cure, but it has so many disadvantages that it is not to be compared with those procedures that stop the inflammatory processes short of the decomposition or death of the exudate. In regard to operating on children, I think the argument cannot be regarded as sound that we should not operate on them on account of the difficulty of keeping a bandage on, for surely if any cases are to be benefited by an operation for radical cure, they are those in which the patient is young enough to grow—in which the tissues can be brought together and retained with great hope of a permanent cure. Everybody knows that cases do recover by the use of the truss, but the proportion, I believe, is less than by any other method. As stated by Professor Gunn, it is found that a majority of operations for strangulated hernia are, in effect, really operations for the radical cure, and there are more than five cures from operations to one after application of the truss. And when we remember that there are 250,000 trusses manufactured per annum in Philadelphia alone, I doubt very much if it can be shown that trusses have even a fair percentage of recoveries following their use.

DR. WM. T. BELFIELD reported a case of
SUPRA-PUBIC CYSTOTOMY WITH EXTRACTION OF LARGE CALCULI, AND CORROSIVE SUBLIMATE POISONING.

The patient was a feeble, emaciated man, 71 years old, who for nine years had suffered from cystitis of steadily increasing severity, caused, as was supposed by his various physicians, by prostatic enlargement. He had been sounded for stone a year ago under chloroform, but with negative result. For two years he had been unable to empty the bladder except by catheter. He refused permission to introduce the sound because convinced that he had no stone, but was anxious to have an operation for the removal of the prostatic enlargement.

June 7, supra-pubic cystotomy was undertaken for the purpose of removing by galvano cautery that portion of the prostate which was assumed to project into the bladder. The introduction of the sound under ether revealed a large stone; the usual incision

was made; the finger in the bladder found two calculi, one behind the prostate, the other adhering to the fundus of the bladder, each about as large as a walnut. The first stone was crushed and the second with much difficulty removed entire. The patient was so collapsed that no attempt was made to remove the prostatic outgrowth, which could have been accomplished without much difficulty, and the following day the temperature was 100.5°, the highest observed. On the third day it was normal and so remained. The wound was irrigated once daily with a bichloride of mercury solution. The progress was entirely favorable until the eleventh day, when there began a severe diarrhoea with much rectal pain and tenesmus, and later the evacuations were tinged with blood and the patient complained of a metallic taste. Sublimate poisoning was recognized and the solution discontinued. Temporary improvement followed, but death ultimately resulted on the thirty-sixth day after operation. No autopsy was permitted, but a hasty examination of the abdominal contents was made. Peritoneum, kidneys and bladder were normal, except that the latter was much hypertrophied. The intestines could not be opened; the calculi weighed 2 ounces and 6 drachms.

THE DEATH OF DR. F. H. HAMILTON.

DR. TRUMAN W. MILLER offered the following resolution, which was adopted:

WHEREAS, This Society has learned with deep regret of the death of Dr. Frank Hastings Hamilton, of New York, and

WHEREAS, In his death the United States has lost one of its most distinguished surgeons; one of its ablest teachers; one of the purest patriots, and, in his private life, one of the most amiable of men; therefore, be it

Resolved by this Society, that we hereby give public testimonial to the many virtues of the deceased, and that we tender his family the assurance of the profound sympathy of this Society with them in the hour of their affliction. And that a copy of these resolutions be furnished them, and a copy spread upon the records.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

Stated Meeting, May 12, 1886.

DR. F. L. KNIGHT, CHAIRMAN.

ALBERT N. BLODGETT, M.D., SECRETARY.

Previous to the papers of the evening, the Chairman announced that Dr. Bowditch desired to address the Section.

DR. BOWDITCH said that he had three articles which he would present to the Section, two of which would be hereafter placed in the portfolio of the Boston Medical Library. They all held important relations with the history of medicine, and he thought they would be interesting to the members.

First. A splendid lithograph of Vesalius, "The

Father of Modern Anatomy." No one could look at it without feeling that if Vesalius had not been great in our profession, he would have been great in any walk of life. One could believe from his fine commanding brow and calm look that he might have been a statesman. He was born in Brussels in 1514, and died in 1564 of starvation in the Island of Zante, where he had been shipwrecked on his return from a pilgrimage to the Holy Land. Accused by the minions of the Inquisition of having begun to dissect a man while the heart was still palpitating, he was saved from death only by the favor of Philip II, to whom he was chief surgeon. He had taught anatomy at Pavia, Bologna and Pisa from 1540 to 1544, and had large crowds of students to hear him. His immortal work, "*De Corporis Humana Fabrica*," in seven volumes, was first printed at Basle in 1543. Boerhaave and Albinus published another edition in folio in 1725 at Leyden.

Second. A pharmacopœia published at Cologne with Petrus Holzeming as editor, a worthy man doubtless, but now wholly unknown to fame, so far as biographical dictionaries are able to tell us. It is a thin folio volume, with large, well engraved title-page. At the top are the armorial bearings of Cologne. Below is a view of the city. On the side, are four physicians, namely: St. Luke, St. Parataban, St. Agmar, and St. Damianas. The last three suffered martyrdom in the fourth century. St. Connes was for many years the patron saint of physicians. A church dedicated to his memory in the thirteenth century was taken down in 1832. At one time the fraternity of priests of St. Connes taught medicine there. Ambroise Pare in the sixteenth century gained his title of Master Surgeon from that Faculty. The pharmacopœia is a most interesting work, as illustrative of the absurd lengths our fathers in medicine went in the number of articles put in their prescriptions. Generally speaking there were one or two active ingredients, as aloe, opium, hyoscyamus, etc., in a prescription, and the remainder were inert. The most remarkable in the book is an electuary powder. It contains fifty-four ingredients and was styled "*Pulvis Subtilissimus*." In this prescription, human nature had evidently gone to the utmost extreme of over-medication. The whole book with its absurd remedies seems to prophesy homœopathy, with its single and equally absurd infinitesimals. Man never goes toward the truth in a straight line, but in a pendulum course.

Third. A photograph of a painting by Watteau, caricaturing in pencil after Moliere had done so with his pen, the absurdities of the faculty and the extremes to which the public were led by eulogiums on the use of the "clystere." Moliere wrote his "*Malade Imaginaire*" for the opera of the king and noblesse. Watteau, coming after him a few years, painted the scenery on the same stage. The painting which the photograph represents is in the museum at Lille, in France. It shows an immense army of people coming to meet the great Doctor, who is dressed in fur-bordered robe, with feathers in his hat. He

stands erect with immense gravity and an important look, his right arm extended as if giving decided directions in regard to a patient who is about to have an enema given to him. An immense crowd looking like an army covers the background, each person armed with a huge syringe, instead of the usual trappings of war. Upon the top of the staff, bearing the color of the regiment, instead of the imperial eagle appears an upturned chamber utensil which shall be nameless. Various groups are seen in the foreground, of a most realistic character. A lady with glutei and legs exposed, and two negroes administering an enema. A lady with her lapdog on her arm and her husband are apparently leaving the scene, but are followed by an attendant of the doctor, armed with a syringe, who is evidently entreating her to allow him to give her an enema. On the other side of the picture is a burly postman, set upon by two attendants, one of whom has pulled the hat over the eyes of the struggling victim, while the other is preparing to give him the injection, which one sees the postman will not readily submit to. But most comical of all is a poor, evidently costive dog, with curved back, plainly striving in vain for a dejection, and mutely appealing for an enema for his relief. One has only to read the "*Malade Imaginaire*" of Moliere, to get a full explanation of this gross caricature. At the same time it shows the absurd length to which our fathers went in regard to the rectum, as according to the pharmacopœia above described, they had a half century or more before, filled the mouths of their patients with their subtle powders. Who can wonder at homœopathy and eclecticism in consequence of such nonsense.

DR. GRACE WOLCOTT read a paper on

A CASE OF ULCERATIVE ENDOCARDITIS.

(See p. 264.)

DR. F. C. SHATTUCK, upon being invited to open the discussion, expressed his interest in the well reported case which had just been read. The pathology of endocarditis in general presents problems at once interesting and difficult, to the solution of which we thought ourselves nearer some years ago than we do to-day. Until lately the real distinction between ulcerative and simple endocarditis was thought to lie in the presence in the former of micrococci, and the term diphtheritic endocarditis was proposed to characterize the process at one time. To these organisms the infectious nature of the affection was attributed; to them it was thought to be due that emboli excited suppurative inflammation about their points of lodgment. This distinction now fails us since Klebs, Köster and others find micrococci in the products of any and every endocarditis, without having succeeded as yet in distinguishing between those accompanying forms which are clinically so different. Anatomically the difference is rather one of degree than of kind, and hence Osler prefers the term malignant to the term ulcerative. In an endocarditis of malignant course there may be no more ulceration than in a benign case of warty endocarditis; and, on the other hand, there may be well-marked ulceration from very different causes. The main anatomical distinction is

¹ Duke Don Nicholas, so called because prepared by an abbot for the son of Don Nicholas.

in the different results of embolism; as to the pathological distinction we are at present ignorant; the clinical distinction is more clearly marked. Thus we are led to the eminently practical question of diagnosis. In some malignant cases the diagnosis may be made with tolerable certainty. We know that the process is especially liable to attack valves which are the seat of changes dependent on previous disease, notably sclerosed valves; and hence grave typhoid or pyæmic symptoms, for which no other cause can be assigned, in an individual known to be the subject of old valvular disease are, to say the least, suggestive. Similar symptoms with indications of embolic abscesses in a case of acute rheumatic endocarditis are, in like manner, suspicious; but this association is, according to Osler, rare. In cases of primary malignant endocarditis the diagnosis may be reached by a happy guess, but is generally beyond our powers. The general symptoms vary very widely in different cases, simulating typhoid fever, pyæmia, malaria, or some other general infectious disease; the leading symptoms may be cerebro-spinal; symptoms pointing to the heart may be wanting or excessively obscure. If the heart was previously healthy the organ is not enlarged and the course of the disease is usually too short to allow it to become so; while a souffle can easily be attributed to so-called dynamic causes. A case which recently occurred at the Massachusetts General Hospital, in the service of Dr. Abbot, the autopsy on which the speaker attended, well illustrates the impossibility of diagnosis at times. A woman died after an illness of ten days or so, with ill-defined but rather typhoidal symptoms and no indication of cardiac disease. Primary ulcerative or malignant endocarditis limited to the tricuspid valve with emboli in the lungs was found. The speaker had seen two or three cases in life in which he had suspected this form of disease, but had not been so fortunate as to secure an autopsy to overturn or confirm the diagnosis. He congratulated Dr. Blodgett both on the diagnosis in the case just reported and on its verification.

DR. E. G. CUTLER expressed much interest in the case reported. He had never seen an instance of ulcerative endocarditis at autopsy, but had had, a few years ago, a patient under his care with the following history; a child of 6 had passed through an attack of mumps, under another physician; two other children were sick with the disease about the same time. Some days afterwards the child, having been all the time ailing, was seized with chills, fever, pain in the præcordia, and restlessness. There was found to be a loud systolic murmur at the apex. The patient got worse, the circulation in one of the arms suddenly ceased, accompanied by pain and swelling. The femoral artery in one of the legs became plugged soon after, associated with severe pain. The murmur ceased before death, which occurred about a week after the patient was first examined.

DR. H. I. BOWDITCH stated that he had never seen a case of this disease in his life, and that the condition was unknown to him. The specimen was a most interesting one, and showed a new source of danger in diseases of the cardiac tissues. Dr. Bowditch asked if the diagnosis of ulcerative endocarditis

were made before death, and if so, on what grounds was this opinion based?

DR. BLODGETT replied that he had the privilege of examining the patient before death, and from the history of a long-continued organic disease of the heart which had been studied by careful physicians for many months, to which a new and most serious complication had been suddenly added, he was led to review the conditions to which this unexpected change might be due. The character of the symptoms observed at this time was essentially that of acute septicæmia; that is, there was acute pain in various parts of the body which were not before the seat of disease. The pulse and temperature were very high, the patient was in a condition of stupor, almost amounting to apathy, and resembled the state called "typhoid" in many asthenic diseases. The array of symptoms thus calling attention to a condition so closely approximating to that of surgical pyæmia, it seems only a short way to the diagnosis which alone would sufficiently explain the symptoms. The autopsy was of necessity very hastily made, and gave no time to examine the other visceral organs, which might possibly have shown other interesting pathological conditions connected with the state of the heart.

DR. SHATTUCK said that in any case of endocarditis we may have embolic formations in the blood-vessels. In benign endocarditis the emboli do not occasion suppuration, while in the form of endocarditis which we may for the sake of comparison call "malignant," the emboli are followed by suppuration, and the appearance of a train of clinical phenomena bearing considerable resemblance to septicæmia.

DR. BENNETT F. DAVENPORT spoke of the
PHYSICAL AND CHEMICAL QUALITIES OF ORDINARY
COWS' MILK,

and added: The question of the age of the milk which is given to our city children I consider as of very much greater importance than it is usually deemed by physicians. There is no fluid that I know of which is a more rapid absorbent of foul odors of all kinds, or which offers a more fertile field for bacterial growths. Yet most of the milk, even when just delivered to the consumers in this city, is already in its third day of age, and has been exposed to a probability of contamination so great that I very much wonder that it does not become downright soured before the time of the next daily delivery. Very much of it is but little short of this stage. I am firmly persuaded that it is to this changed condition in the milk, to which city folks have become so accustomed as to consider it the proper and natural condition, that a very large proportion of the summer diarrhœa and the resulting mortality among the children in our cities is due. If any one wants ocular proof of the grosser forms of contamination to which city milk is exposed, he has but to visit any of the larger milk depots of the city, and to look at the nature and the quantity of the foreign material left upon the cloth strainers connected with the centrifugal machines used for separating the cream from the surplus milk of the day. If he does not then learn by seeing with his own eyes what he could otherwise hardly be brought to believe to be

possible, I am very much mistaken as to what are the real facts. Very fortunate indeed would it be, if only the firm and already dissolved impurities could also be thus readily separated out from the milk.

We, as physicians, have learned to know that milk about upon the point of changing will more disturb the digestion of a child than that which has already turned sour. I believe that the difference in the coagulation of breast and cow's milk in a child's stomach is more owing to the difference in the chemical reaction of these two milks, and in the amount of albuminoids contained therein, rather than to any difference in the nature of these albuminoids, for cow's milk, even when fresh, is of an acid reaction, while breast milk is neutral, or may be slightly alkaline. Then, too, cow's milk contains a much larger amount of albuminoids. Making cow's milk of a neutral or slightly alkaline reaction will render this curd finer and softer, and this is also accomplished by diluting with fluids or with soft solids, for which barley flour or malted extract serves well.

When it is desired to add cream to the diluted and sweetened milk when prepared for a child, I think it is better here in the city to use sweet cream raised by the centrifugal machine, rather than that obtained by separation from standing, which necessitates it being just so much the older, when one of the chief troubles is that it is already too old. Such sweet cream is to be had of the large milk depots in the city.

I think that if physicians would instruct all their patients to demand that milk be delivered to them the same day that it is brought into the city from the country, this would become the more common custom of the trade, and that there would be a marked decrease in the infant mortality during the summer months, for if we cannot secure proper cleanliness in the care of the milk, we might at least thus shorten materially the time during which fermentative contaminations would have a chance to work out their harmful changes.

DR. GEORGE W. GALVIN exhibited an
IMPROVED INHALER,

which he described as follows: The inhaler is the invention of Dr. Geo. A. Evans, of Brooklyn, New York, and a full description of it, with a group of cases treated by him, was published in the *New York Medical Journal*, March 6, 1886. The great obstacle to overcome in the local treatment of pulmonary diseases, is the condensation of the vaporized medicament in the mouth, pharynx, and upper air passages. This has been overcome by Dr. Evans's instrument, which can reduce any fluid medicine or solution to so fine a degree that it can pass the bronchial tubes without condensing and reach the air cell of the lungs in which is stored the residual air. The changes in the lungs in pulmonary phthisis bring consolidation, tissue necrosis, putrefaction, decomposition, and septic absorption (I am not now considering tubercle, its nature, etc., but what is considered pulmonary consumption); it is natural to suppose that if we can convey to the lung an antiseptic vapor which will reach the part undergoing the pathological changes, we should obtain practical results from the local treatment of pulmonary affections.

The apparatus consists of an air condensor, an air chamber (flask) for preserving a continuous current of air, a three-mouthed bottle, "Wolf's;" a spray chamber having three mouths; spray tubes; respiratory tube; mouth-piece.

A spray of the solution in the bottle is thrown (by means of compressed air), against the opposite wall with sufficient force to produce a thorough churning with the atmospheric air, a fine vapor, resembling cigar smoke, which escapes through one of the openings in the glass air chamber to the respiratory tube.

During inspiration through the mouth-piece, air enters the middle mouth of the bottle and displaces the vapor of which the bottle is full. During expiration the air in its turn is displaced, passing out of the middle mouth of the bottle, to make room for the vapor which passes from the glass air chamber to the bottle, where it accumulates for the next inhalation.

A vapor produced by means of this apparatus condenses slowly, fifty cu. in. of a vaporized solution, containing carbolic acid, borax, glycerine and water, requiring twenty minutes of a temperature of 60° F. to entirely condense.

Ten cases are now reported in this journal with a cessation of symptoms which leads the patients to consider themselves cured. One case of my own far advanced in the second stage of chronic catarrhal pneumonia, after ten inhalations has gained in ten days two and one-half pounds, and to all intents and purposes is making a rapid recovery.

DR. W. EVERETT SMITH then exhibited a

SEMPLE'S ATOMIZING INHALER

which he has been using in connection with Williams' Pneumatic Cabinet. This inhaler was devised by Wm. F. Semple, of Mount Vernon, Ohio, in August, 1881, and consists of a glass receptacle containing an ordinary atomizer. The medicament is held in the bottom of the jar and is atomized either by a rubber hand bulb or more effectually by a cylinder of compressed air. The spray is projected against the top of the jar, the larger particles are condensed to be re-atomized and only the very finest portions of the spray escape through the inhaling tube.

The vapor thus inhaled has been so churned as it were and broken up that it is as fine and impalpable as smoke, and indeed resembles it in appearance. The mouth-piece to the inhaling tube can readily be removed and attached to a flexible rubber tube so that the vapor can be conducted wherever and in whatever direction one pleases. Any fluid that is readily atomized may be employed, the best menstruum being either fluid petrolatum or a 20 per cent. solution of glycerine in water. The resulting vapor will resist condensation for from five to fifteen minutes.

The atomizer was shown to be identical in its principles of construction with the Evans' Inhaler that was exhibited by Dr. Galvin, and when attached to the cylinder of compressed air produced as fine and perfect a vapor as Evans' apparatus. It has, however, these differences in its favor—is simpler in its construction, more easily cleansed and was perfected and in use four years before Dr. Evans set up his claim; yet Dr. Evans calls his atomizer a "new instrument."

Further than this, Dr. Evans in his article in the *New York Medical Journal* of March 6, 1886, makes no mention of and gives no credit either to the Semple Inhaler or to the Globe Inhaler of Beseer.

Dr. Evans' apparatus is faulty in two particulars; the inhaling tube is long and is complicated with three glass globes which must be kept thoroughly antiseptic if we are to assign any dangerous activity to the numerous germs of disease. The patient under treatment must moreover inhale and likewise exhale through this one tube, the three glass globes and the Wolff bottle which contains the medication; each patient ought therefore to have an entire atomizer reserved for his own particular use, since it would be practically impossible to cleanse *thoroughly* all this complicated arrangement after each application.

Dr. Evans claims, however, as an advantage in favor of his apparatus that the vapor will resist condensation for twenty minutes. But is easily demonstrated that with any form of atomizer constructed upon these principles, the increase in the resistance to condensation depends *directly* upon the increase in the specific gravity of the fluid atomized and not upon the particular *shape* of the atomizer.

The very fact, however, that the vapor refuses to condense for so long a period as twenty minutes is an objection rather than an advantage to the method of treatment. Everyone grants that ordinary atomizers are of little benefit in the treatment of lung diseases, because the vapor from them condenses almost entirely upon the mouth and pharynx. At the same time no physician would demand that a patient suffering from pulmonary phthisis should actively inhale a medicated vapor longer than twenty or twenty-five minutes at any one time because of the physical exhaustion that would follow a longer treatment. If then the vapor that is inhaled resists condensation for so long a period as twenty minutes, Dr. Smith claimed that it is *just beginning* to be deposited upon the bronchial tubes when the treatment is stopped. He had been better satisfied with the results obtained by a vapor that did not resist condensation for nearly so long a period as that claimed by Dr. Evans.

At the same time Dr. Smith claimed it to be a fallacy that by the use of either the Semple or the Evans' Inhaler atomized vapor can be deposited upon *lung cells*, especially if they are diseased so that they are unable to be readily expanded. The vapor when finally churned in these inhalers may be deposited and very likely is deposited upon the larger bronchial tubes, but we must remember that bronchial tubes are very different from air vesicles and that the volume of air which we ordinarily breathe—the *tidal* volume—reaches *directly* only the trachea and large bronchi, but enters the air cells in obedience simply to the law of the diffusion of gases.

Unless, therefore, some of the external pressure of the atmosphere be removed from the chest walls, as it is in the Williams' Cabinet, so that the *complemental* volume of air can be inhaled *involuntarily* into even remote air vesicles, the only medication that can effectually reach any decided area of lung cells must be gaseous in form. But however finely you may divide aqueous vapor under ordinary conditions of

temperature and atmospheric pressure, you cannot make it gaseous, for a gas is not condensed except under enormous pressure and at exceedingly low temperatures.

Dr. Smith accordingly, while praising the inhalers that were exhibited, maintained that to derive their greatest benefit they should be used in conjunction with some form of the Pneumatic Cabinet. He has used the inhaler with the cabinet since last December, and has found the results to be highly satisfactory and encouraging.

DR. BOWDITCH said that one of the important objects of any inhaler was to force the substance to be inhaled into the pulmonary structures as much as possible. Whatever the arrangement for inhalation may be, the object to be attained is the pulverization of the substance, and its forcible propulsion into the lungs. The inhaler shown by Dr. Smith is always employed in conjunction with the Pneumatic Cabinet, as an aid to its introduction or propulsion into the deeper parts of the pulmonary recesses.

DR. KNIGHT stated that the instrument exhibited by Dr. Galvin was capable of producing a finely pulverized fluid, and he had never seen anything so fully answering this demand as the one shown at this meeting.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, May 19, 1886.

VICE-PRESIDENT, WM. H. TAYLOR, M.D.,
IN THE CHAIR.

T. E. MCARDLE, M.D., SECRETARY.

DR. BERMANN presented a bottle full of

POLYPI REMOVED FROM A PATIENT'S NOSE,

where they had been growing for the past seven or eight years. The turbinated bones were atrophied and the septum driven to one side. Some of the tumors were gelatinous, but most of them were of a fibroid character.

DR. JOS. T. HOWARD read a paper on

UROGLAUCIN.

About 1845 Heller discovered in urine a peculiar substance which he called uroxanthine, which, by further treatment with acid reagents at a high temperature, yielded a blue uroglaucon and a red pigment, urrhodine. These coloring matters, he proved, were similar to those which had been previously discovered by Braconnot, in the urine, composing a substance which he (Braconnot) called cyano urine, and Virchow and Kleitzinsky showed the identity of urrhodine with indigo red, and uroglaucon with indigo blue. It is the latter, apparently, occurring in the urine of a patient under my care, that it is proposed to speak of now. I say apparently, because the sequel may prove it to be something else; consequently, before detailing the case it may be of interest, if not edifying, to briefly consider the history and sources of "indigo blue," with its relation to the urine generally.

Indigo blue was first mentioned by Dioscorides as

indikon, next by Pliny as *indicum*. When first introduced into England it was called "indico." The principal source of this familiar coloring matter is, as you well know, the numerous indigiferous plants, mainly the *indigifera dinctoria*, anil, *satisneurium* and *polyganum*. In the process of manufacturing indigo the plants are steeped in water for a few moments, and after their removal from the liquid the latter is exposed to the air and frequently agitated to facilitate the absorption of oxygen, which produces the blue color in the water. If the water be allowed to rest awhile indigo is deposited as a pigment insoluble in water, alcohol, oils, dilute alkalies, and hydrochloric acid, but if slowly heated it volatilizes in purple vapor, which afterwards becomes condensed in delicate crystals, the chemical composition of which is expressed by the formula, $C_{16}H_8NO_2$.

In the urine, as stated by Heller, indigo was found in combination with urrhodine, forming the compound uroxanthine; from which his process of extracting uroglaucin was somewhat as follows: Urine recently voided is mixed with a hot solution of acetate of lead filtered and freed from an excess of the acetate by sulphuretted hydrogen, and boiled to free it from excess of the latter. The hot fluid is now constantly stirred and gradually added to an equal volume of concentrated fuming hydrochloric acid, which, if uroglaucin be present, should cause it to assume a greenish and very dark blue color. If the mixture assume a violet or red tint only, no indigo is present. If it does become blue, as just stated, and is allowed to stand for some time, a copper-red, shining, metal-like, dark crystalline pellicle appears upon the surface. After twelve hours the fluid is diluted with an equal portion of cold water, well agitated, and put aside for twenty-four hours, when a heavy deposit is formed which is separated by filtration and washed with boiling water until the washings have a neutral reaction; it is then washed with dilute spirits of wine and dried over sulphuric acid in the water stove. The dry filter is now washed with pure ether as long as any red color, urrhodine, can be obtained. For this purpose large quantities of ether, and a proportionate amount of time, are required to get rid of the urrhodine. Next, all that portion of the filtering paper which shows no blue deposit is cut off, and the remainder, divided into small pieces, put into a balloon and boiled strongly with absolute alcohol. As often as the alcohol assumes a sky blue, or greenish, color, it is poured off and a new portion added until, by protracted boiling, it becomes entirely colorless. The alcoholic extract, which has an acid reaction, is filtered whilst boiling hot, then evaporated down to one-half, and put aside in a well-stoppered bottle. When the fluid cools uroglaucin is deposited in spider-like petaloid.

The first record of blue coloring matter occurring in the urine is attributed to James Planeus, 1767; the first chemical description of a blue or violet coloring matter being found in the same was given by Braconnot, who, as before mentioned, called it cyanourine. In one of Braconnot's cases the urine, voided with difficulty, was of an intense yellow, which after standing gave a blue deposit. He relates another

case reported by M. Julia, in which the blue color was attributed to the presence of prussiate of iron. (See *Ann. de Chem. de Phys.*, xxix, p. 252.) Braconnot was followed in his discovery by Heller, Prout, and others.

Now in no instance on record, so far as I have been able to ascertain, except, perhaps, the cases of James Planeus and of M. Julia, can it be inferred that indigo was ever found spontaneously dissolved in the urine, but when present in that fluid was discovered only after a long and tedious chemical process such as has been detailed above; nor is there any account given of a simple blue urine having been emitted; consequently the case that I now present is the third, if not the first, to be chronicled in which urine of a dark blue color has been voided. For such indeed it was at that time, and did not become blue from decomposition after standing, as was the case mentioned of Braconnot, and which it might have done in that of M. Julia, either within the bladder or after emission.

It is hardly probable, in the case now presented, that the change occurred whilst the urine was within the bladder, because the patient had, but a very short time before voiding the blue, passed a clear-colored urine; evidently, then, it was not in that vessel sufficiently long to undergo fermentation, although indican possibly may have been present in the urine previously passed without attracting attention, for Schunck says: "Urine containing uroxanthine exhibits no remarkable or peculiar appearance whatever to the naked eye; it is acid clear and of the usual color." This learned investigator found indican so often in urine that he concluded it must be a normal constituent of the fluid. Heller, however, found it most frequently in persons with disease of the kidneys and spinal cord—a circumstance which, as regards the last mentioned, coincides more nearly with the pathological condition of my patient, who for some time had been laboring under a severe attack of sciatica, in which the medulla spinalis, or its appendages, were more or less involved.

The following is the case: W. R., æt. 63, tall, of a spare frame, and sanguino-melancholic temperament, general health good, complained of great pain in the back and down the left lower extremity along the course of the great sciatic nerve and its branches, which, after a regimen of counter irritants, purgatives, and alteratives, showed signs of abatement and gave promise to the patient of an early recovery. One day after the usual morning visit, at which time all things seemed to have been progressing favorably, I was sent for in great haste, and upon entering the chamber of the man found him and his family in great consternation and, perhaps, some little alarm, on account of the blue urine exhibited, which the patient had but a short time before passed. Observing the anxiety of his distressed wife, and others around him, the invalid affected to treat the matter lightly, and jocosely remarked that he "had often heard of 'blue bloods,' but was not before aware of his being one of them." Although unable at the time to explain the phenomenon, I was satisfied from the patient's general condition that there was no cause for

uneasiness regarding him, and so expressed myself. Upon examining the urine I found it to be of a deep indigo-blue color, and being assured that it had been voided in that condition I was satisfied. If proof had been necessary it was present in stains upon the bed linen.

I very much regret that a portion of this urine was not taken for chemical investigation. How indigo is obtained from indigiferous plants, uroxanthine, and the urine itself, has already been explained; perhaps, by reverting to that part of the subject we may be obtain at least a negative clue to its formation in the case before us. The improbability, in my case of the blue color having resulted from decomposition of the urine within the bladder, or after it passed into the bidet, has been considered, and we know it was not subjected to any chemical process similar to that before detailed. Then, from whence came it? Perhaps it originated in the alimentary canal and was taken up by the absorbents through which it found its way into the blood, causing the patient to be, as he indeed supposed himself, blue blooded; from the blood it was eliminated by the kidneys, passed into the bladder, and from thence into the vessel. This is a very rational conclusion, when we consider the fact that the patient had been for some time taking iodide of potash, and having taken a meal that morning composed principally of amylaceous substances, it may be that some of the iodide remaining in the stomach was decomposed by the gastric juice setting free the iodide, which, coming in contact with the starch in solution struck the blue color which was imparted to the blood in the manner indicated. This deduction is sustained by the well-known fact that one millionth part of iodine will give the blue color to a solution of starch outside of the body; from which it may be reasonably inferred that, in the instance in question, the same reaction occurred within the body; but if this be the case, was it uroglauclin or simply a blue color?

DR. ACKER had seen one such case in an hysterical woman who was suffering from chronic Bright's disease. She passed a pint of urine of a decidedly blue color. Uroglauclin has been discovered when disease of the alimentary tract is present; also in granular disease of the kidney.

DR. W. W. JOHNSTON presented a specimen of
PERITONITIS IN TYPHOID FEVER, WITHOUT PERFORATION.

DR. A. Y. P. GARNETT disagreed with Dr. Johnston as to the diagnosis. The only specific evidence present was slight enlargement of Peyer's patches. Was there not some tubercular degeneration of the mesenteric glands? Peritonitis may occur in many ways and from many causes.

DR. JOHNSTON contended that the characteristic lesions of typhoid fever were present. There are no determining symptoms except a morning decline and an evening exacerbation, together with the duration of the fever. Of course all local inflammations must be excluded. In the case under consideration the fever had lasted two weeks, with a morning decline and an evening rise of temperature. At the autopsy

he found enlarged and inflamed Peyer's patches and solitary glands. There was also acute enlargement of the mesentary glands.

DR. TAYLOR remarked that John Harley declares that in the Delta of the Mississippi some cases of malarial fever are found which cannot be distinguished from typhoid fever, because ulceration of Peyer's patches is present.

DR. JOHNSTON said he would include such cases under the head of typhoid fever.

DR. D. S. LAMB presented a specimen of
PYO-SALPINX.

Uterus and appendages covered generally with lymph. Right Fallopian tube, distal portion, dilated and filled with pus, which readily escaped from fimbriated end, on pressure, into peritoneum. Ovaries showed small aqueous cysts.

From Mrs. C., aged about 35. A few hours after a fright on April 27, she had acute pain in the abdomen, followed by general peritonitis, and death one week afterwards. The necroscopy showed the intestines distended with flatus, all the abdominal viscera more or less united by adhesions, and a large quantity of pus in the cavity. The explanation of the case seems to be that the pus from the Fallopian tube found its way, at the time of the fright, into the peritoneal cavity and set up general inflammation, from which she died.

DR. LAMB also presented a

LARYNX AND PORTION OF TRACHEA OF GENERAL
TUBERCULOSIS.

They were taken from a man aged about 30, who had general tuberculosis. The mucous membrane shows many tubercles of the size of small pin heads, projecting from the surface; large ragged ulcer on under surface of base of epiglottis; another on each vocal cord, which was nearly destroyed; one on left cricoid, and several in trachea.

Necroscopy.—Much emaciation; dura mater normal; arachnoid showed numerous opacities, especially over sulci of convexity; Pacchionian bodies abundant along longitudinal sinus; pia mater along each middle cerebral artery showed minute tubercles, thick lymph and adhesions; there was lymph also on upper surface of left cerebellar hemisphere near median fissure. Brain substance generally consistent and normal, but fornix softened to a pulp; softening also on under surface of right optic thalamus; ventricles much dilated and full of turbid liquid; right choroid plexus indurated; small cavity in pineal gland. Lungs showed old adhesions, especially at apex of right: filled with miliary tubercles; large vomicae in upper lobes. Liver normal. Spleen somewhat lobulated, firm old adhesions. Pancreas normal. Stomach not opened. Small intestine; lower portion showed ulcers, mainly occupying Peyer's patches, varying in size, and having the long diameter parallel with intestinal axis; corresponding peritoneum covered with minute tubercles and bands of adhesion. Vermiform appendix showed hour-glass contraction about midway of the tract; mucous coat of that portion opening into caecum was deeply ulcerated; terminal portion nearly closed by the con-

traction named and filled with pus; its mucous membrane entirely destroyed by ulceration. Cæcum showed ulceration. Mesenteric and gastro-hepatic glands enlarged. Suprarenal capsules showed small tubercles (?). Kidneys normal. Bladder distended.

MISCELLANEOUS.

INTERNATIONAL CONGRESS.—The subject of Public and International Hygiene is likely to occupy an important place in the discussions of the ninth International Medical Congress, or rather of its fourteenth Section. We are glad to see that Mr. Simon is anxious to attend the Congress and take Vice-Presidency of the Section. Mr. Simon, indeed, speaks in his letter responding to the invitation with some doubt as to his power to attend, but with a clear intimation of his desire to do so. Dr. B. W. Richardson and Dr. Thudichum both reply in most cordial terms to similar invitations, and accept a similar office. To those who know the imperfect health which Mr. Simon has lately enjoyed, the significance of his conditional acceptance is very great. The promoters of the Congress will take this as a sign of British good will towards their great and responsible undertaking. The important subject of International Quarantine is to be raised by the president of the section, Joseph Jones, M.D., of New Orleans. We could send to the discussion of such a subject no greater authority than Mr. John Simon. We are glad to be able to report a very general desire among leaders in London to be present at Washington in 1887. Whatever hesitation they felt some time ago in view of the divided state of feeling in America is now steadily giving place to a desire for the success of the Congress, and a wish to do anything they can to further it. We feel quite justified in saying that our best men in England and Scotland are preparing to go if they get any indication that their presence will be acceptable. Sir Andrew Clark, Sir Spencer Wells, Professor John Chiene, Professor Fraser, and we believe Sir William Turner, are all, according to our information likely to go.

It is not America alone that is interested in the success of the meeting at Washington, but the profession throughout the whole world, and we might add the world itself. When our profession meets internationally it is of good omen. We not only stimulate fraternity and scientific rivalry amongst ourselves, but every thought in advance and every medical discovery is a great boon for the human race and for all nations. We urge on members of our profession in the empire to strain a point to be at Washington on or before September, 1887, where, if report is to be trusted, a very hospitable reception awaits them.—*Lancet*, August 7, 1886.

THE HYGIENE OF THEATRES.—Given a spacious theatre, crowded during an evening performance for a period of hours, what is the difference of the effects on its atmosphere produced by the electric light or by gas, particularly as to the temperature and the

generation of carbonic acid? Such is the problem which Dr. P. Renk, Professor of Hygiene at Munich, has just set himself to solve. Taking the Theatre Royal of that city, which is lighted by 1400 lamps on the Edison system, he tested the two kinds of illuminants, with the following results: During a representation which lasted from 5:30 P.M. to 10:15 P.M., and was witnessed by 1790 people, he found that while the rise in temperature in the pit was 11.1° C. with gas, it was only 7.7° C. with the electric light, and that in the upper gallery it was 10.7° with the former, and not more than 7.4° with the latter. As to the increase in the production of carbonic acid, the results were equally important. In the pit it was 2176 with gas to 1221 with the electric light, and in the upper gallery as 2855 with the first to 1430 only with the second.—*Medical News*, July 24, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM AUGUST 21, 1886, TO AUGUST 27, 1886.

Major A. A. Woodhull, Surgeon, granted leave of absence for fourteen days, to take effect on or about Sept. 1, 1886. (S. O. 197, A. G. O., Aug. 25, 1886.)

Major M. K. Taylor, Surgeon, leave extended one month. (S. O. 195, A. G. O., Aug. 23, 1886.)

Capt. J. V. Lauderdale, Asst. Surgeon, granted leave of absence for two months, with permission to apply for one month's extension, when his services can be spared. (S. O. 195, A. G. O., Aug. 23, 1886.)

First Lieut. Chas. M. Gandy, Asst. Surgeon, on expiration of his present leave of absence, relieved from duty in the Dept. of the East, and assigned to duty in the Dept. of Texas. (S. O. 195, A. G. O., Aug. 23, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING AUGUST 28, 1886.

Clark, John H., Medical Inspector, ordered to special duty, Portsmouth, N. H., and Widow's Island.

Kindleberger, D., Medical Inspector, ordered to hospital, Washington, D. C., Oct. 1, 1886.

Gihon, A. L., Medical Director, ordered to hospital, Mare Island, Cal., Oct. 15, 1886.

Robinson, Somerset, Medical Inspector, detached from hospital, Mare Island, Cal., Oct. 15, 1886, and wait orders.

Spear, J. C., Medical Inspector, ordered to Naval Laboratory, New York, Sept. 28, 1886.

Bloodgood, Delevan, Medical Director, ordered to hospital, Norfolk, Va., Sept. 29, 1886.

Taylor, J. Y., Medical Director, ordered to Naval Laboratory, New York, Sept. 29, 1886.

Dean, R. C., Medical Director, detached from Naval Hospital, New York, and wait orders.

Simon, W. J., Surgeon, detached from U. S. S. "Constellation," and special duty at Naval Academy, Annapolis, Md.

Henry, C. P., Asst. Surgeon, ordered to hospital, Philadelphia, Pa.

Pitts, H. B., P. A. Surgeon, detached from hospital, Philadelphia, Pa., and wait orders.

Stone, E. P., Asst. Surgeon, ordered to receiving ship "New Hampshire."

CORRIGENDUM.

In Transactions of the Chicago Gynecological Society, June 18th—appearing in the last issue of *THE JOURNAL*—Dr. Wm. H. Byford is reported to have read a paper entitled "A Study of the Cause and Treatment of Pelvic Hematocœles." Dr. H. T. Byford was the author of the paper.

CLINICAL ASPECTS OF RENAL CANCER, WITH REPORT OF TWO CASES.¹

BY JOHN A. OUCHTERLONY, A.M., M.D.,

OF LOUISVILLE, KY.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND CLINICAL
MEDICINE IN THE MEDICAL DEPARTMENT OF THE
UNIVERSITY OF LOUISVILLE.

Malignant disease of the kidneys, regarded from a clinical point of view, occurs either as a primary or secondary lesion. Clinically the latter is of little importance, and the present study will be confined to the primary form. For various reasons the subject is of more than common interest:

First.—This lesion is quite rare, and our knowledge of it dates back only to very recent times. When Valleix¹ published his work in 1853, so few cases of renal cancer had been observed that he remarked: "One may say that no authentic case has occurred where malignant disease was limited exclusively to the kidney. Roberts² has been able to contribute only four cases as the result of his personal observations. During twenty-two years there were only fifteen cases of malignant renal disease in Guy's Hospital, London. All writers agree as to its infrequency.

Second.—The great diversity of the symptoms and the course of the disease render the clinical aspects of it varied, and sometimes not a little difficult.

Third.—The number of other pathological conditions which more or less resemble it, incite the clinician to increased vigilance and care in diagnosis, and add new pleasure to his efforts.

Fourth.—The difficulties encountered in the diagnosis are often very great, and the errors which have been recorded are quite numerous. Bright declares that among abdominal tumors, few are so difficult to recognize as tumors of the kidneys.

Cancer of the stomach and of the liver, pregnancy, ovarian tumors, enlargement of the spleen, abdominal aneurism, have all been pronounced as present in persons who afterwards were found to have malignant disease of the kidneys. More than forty years ago Rayer³ called attention to a class of cases in which renal cancer remained entirely latent through-

out its whole course to the fatal termination. Between this class and that in which characteristic tumor, pain, and hæmaturia distinctly signalize the disease, there are numerous cases in which the clinical phenomena group themselves in the most strange, unexpected and puzzling manner. May I not, then, venture without presumption to occupy this learned body for a few minutes with the clinical aspect of so important and interesting a malady, and one which, owing to the boldness and the genius of modern surgeons, has recently acquired new claims to our attention from a therapeutic standpoint:

Etiology.—The causation of malignant, renal disease has been but imperfectly elucidated by clinical investigation. That it may be congenital, seems likely from Dr. Williams's case of myo-sarcoma of the kidney, reported in the Transactions of the Pathological Society of London for 1881. The irritation of calculi appears in some instances to have been the starting-point of, or to have roused into activity a hitherto latent tendency to the disease. In the *Transactions of the Pathological Society of London*, for 1881-82, Coupland reported a case of medullary cancer of the kidney, associated with calculi, and another similar case appeared in the same volume, reported by N. Moore. It is also not improbable that a wider experience will show a certain relation to exist between the condition known as floating kidney, and malignant disease of this organ. Such association was recently observed by Dr. R. Wernacke,⁴ of Buenos Ayres. In the *London Lancet* for 1885, Dr. J. B. Pollard recorded a case of carcinoma and dilatation of the kidney from which he had removed a large number of calculi during life.

Age exerts a powerful influence here, as in malignant diseases elsewhere. Although histological considerations are purposely avoided in this paper, it may be stated in passing that sarcoma of the kidney is more frequently encountered in children. Yet primary sarcoma is very rare in the kidney as well as in other glands. J. Bokai, of Buda Pesth, recorded in 1884 the case of a boy only 1½ years old with sarcoma of the kidneys. In 1883, Dr. Alloway published in the *Philadelphia Medical News* the case of a sarcoma of the kidney in a child. But this is not always the form met with in childhood, as shown by J. J. Topliff's case of encephaloid of the kidney in a boy 7½ years old. (*Denver Medical Times*, 1884.)

External violence certainly seems to exert some

influence in the production of malignant disease of the kidneys. It is impossible as yet to decide in what manner, or degree, blows upon the abdomen, or falls, or other injuries exert this power. Brinton, Manzolini, Jerzykowsky and Chomel report cases illustrative of this point, and I have myself observed a case in which a fall was followed within three months by phenomena culminating in well-defined, malignant renal disease. An interesting fact in this connection is that in some of the cases reported the malignant disease did not manifest itself until years after the injury had been received.

Primary cancer of left kidney, secondary implication of the right kidney, and ascites.

Case 1.—Primary cancer of left kidney, secondary implication of liver and right kidney, and ascites.

Willie Lairing, aged 6 years and 9 months, was brought to me on the 7th of October, 1883. Two years ago he had measles, but not very severely, and sometime before he had whooping cough, which lasted two months. He had completely recovered when attacked with measles. About a year ago he had a fall, and his side struck against a large stone. He complained at the time, and cried from pain for a day or two. Nothing more was remarked except that his mother thought that he had fever now and then. Nine weeks prior to his visit to me his mother noticed a lump in his left side. It was hard and not tender under pressure. During the last winter he passed bloody urine for several days; hæmaturia returned in the Spring, and again a few days before his coming to see me. About three months ago he began to complain of pain at the pit of the stomach, generally more in the morning, but has been free from it for several days. He has lost flesh; appetite bad, but is now improved; bowels were constipated until recently, when, as a result of medicine they have acted regularly. He sleeps well.

Present Condition.—Rather sallow and thin, but

not markedly anæmic. The tongue clean; pulse 90; respiration 20; temperature 99 Fahr. The liver is enlarged and somewhat nodulated. In the left iliac and hypochondriac region there is a hard nodulated tumor, which descends to the iliac crest; anteriorly it reaches nearly but not quite to the median line. It is immovable and does not descend with the diaphragm. On the outer and posterior aspect of the tumor, is a rather soft and oval prominence, which is probably the spleen somewhat displaced, and compressed between the tumor and the abdominal wall. There is moderate ascites, and numerous enlarged superficial veins coursing over the abdomen. The right kidney is also enlarged.

Heredity, which figures so conspicuously in the etiology of cancer in general, seems to be without influence in developing cancer in the kidney. I have only found a single case in which hereditary tendency to cancer could be traced. This occurred in a patient aged 45 years, whose mother had died of cancer of the stomach. (Case of Malignant Tumor of the Kidneys. Dr. John C. Thorowgood, *Med. Times and Gazette*, Nov. 7, 1868.)

Sex appears to have a marked influence, as the great majority of cases have occurred in males.

Symptoms.—A study of the cases which have come under my own observation, and analysis of those which have been published, have convinced me that a classification of renal cancer upon a natural and clinical basis is rather difficult. The simplest and most practical division would perhaps be into regular, irregular and latent.⁶ It is true some cases which have been described as latent were characterized by tumor, as in the patient of E. Gaucher. (*Bull. Soc. Anat. de Paris*, 1882.) The kidney was the seat of encephaloid, had reached double the normal size of the organ, and was never made out during life. There was a general cancerous infiltration of the peritoneum, abdominal pain, digestive derangement, frequent vomiting, alternating diarrhoea and constipation, and rapid emaciation. Nevertheless, it must be admitted that an undoubted carcinoma of the kidney may run its course to a fatal issue, without revealing its presence by pain, tumor, hæmaturia, or any other urinary disturbance. An acute diagnostician may suspect internal malignant disease, but without finding any facts to indicate its site. Such an instance is related by M. F. Colleville (*Bull. Soc. Anat.*, Jan., 1883), and is the only case, I believe, on record which can properly be called *latent*.

For practical purposes, then, renal cancer may be said to present itself under two forms:

First. The regular or typical form, which, as in other diseases, embraces the smaller proportion of cases.

Second. The irregular form, constituting the greatest number, but the irregularities, or deviations from the regular type, are manifold and varied.

It would be both interesting and profitable to undertake a subdivision of this class, were the reported cases in sufficient number; but this must be reserved for the future and probably for some other person than myself.

⁶ Patino Luna, *Formes Clinicales du Cancer Rénal*, 1884.

Even in a typical case the access of the disease is insidious. This is especially the rule where it runs a protracted course; but, on the contrary, where rapid in its progress, the development is characterized by a certain degree of acuteness. Roberts mentions ten weeks as the minimum duration observed; and Ebstein found that the period during which objective symptoms could be observed was only five weeks.

Pain is usually the first symptom in point of time; not easily described by the patient, not localized, but radiating. It may be continuous, or occur in more or less severe and protracted paroxysms. As the morbid growth increases in size, exerts pressure upon, and contracts adhesions to neighboring organs, neuralgic pains may be caused, which are more properly regarded as complications than symptoms of the renal disease.

Hæmaturia is often enough the earliest indication that anything is amiss. It may continue for a long period, but is more frequently intermittent, and recurs again and again at irregular intervals, often enough so profuse as to be alarming, and certainly may prove a cause of exhaustion. It may in other cases be so slight as to require the aid of the microscope for its detection. In some instances this symptom comes on quite late, as in the case reported by Townsend,* where it preceded death by only three days. The loss of blood is painless, and in this it differs from the bloody urine of renal colic.

The urine usually presents nothing abnormal, save while hæmaturia is present, when albumen, clots and blood casts are likely to be found in it.

The development of nephritis is attended with urinary changes which are indications of this complication rather than the original disease.

In the earliest stage tumor has not yet been formed; a little later it may still be too small to be detected. But sooner or later it generally becomes accessible and possessed of certain characteristics. In the vast majority it is unilateral, having its centre opposite the lumbar region, between the costal arch and the iliac crest. It does not descend with the diaphragm. It is sometimes perfectly smooth and uniform, but more frequently irregular, and nodulated, hard and fixed. Occasionally some parts of it are hard and others soft.

I am under obligations to my friend, Dr. Ewing Marshall, of Louisville, Ky., for the notes of a case of cancer of the right kidney in a boy 15 years of age, in which the tumor filled the abdominal cavity, and presented a uniformly smooth fluctuating surface. On aspiration a pint of purely sanguineous fluid was withdrawn.

The growth may attain huge proportions, as in the case of Roberts in which it weighed over twenty-five pounds. The abdomen becomes proportionately distended. The lower ribs become spread out and increase the general deformity.

The appetite varies, but is generally impaired. The bowels, often enough compressed, are persistently constipated, but sometimes irritation is set up: there is alternately diarrhœa and constipation,

and sometimes mucus and bloody discharges. Emaciation may be very gradual, but is apt to be steady, and periods of temporary arrest are very rare. It may become extreme.

The temperature, according to my own observations, was somewhat above the normal, but others (Fagge) have found it either normal or somewhat lower.

Case 2.—Albert B., aged 34 years, born in Ireland, served as a soldier in the army from 1869 to 1874; a carpenter, married, temperate, consulted me on the 6th of June, 1884. Ten years before he had several ulcers of the penis, with suppurating buboes in the groin, but no constitutional symptoms have ever ensued. Nine years ago he had ague which lasted three or four weeks, and he has never been quite well since that time. Seven or eight months after this last illness he first noticed that something was growing in his right side, which has remained ever since, and has increased in size, and becomes the seat of pain, when he assumes an erect position or lies on the side.

Present Condition.—Patient's height 5 feet 9½ inches. Eight months ago his weight was 148 pounds, and he thinks he has not lost since then. Pulse 94, respiration 18, temperature 99¼° Fahr., appetite good. He sometimes swells up after eating, and suffers a good deal from flatulence. The bowels are loose, and sometimes move ten or fifteen times in the twenty-four hours. The passages are thin, small, and contain mucus pus and blood, and are accompanied with tenesmus. No hæmaturia has been observed, nor anything abnormal with the urine.

On percussion the area of dulness on the liver

* Dublin Quarterly Journal, 1868.

and spleen were found normal. A tumor was found occupying the right flank, extending from very near the inferior border of the liver, and separated from the latter by an appreciable space, it appeared to occupy the site of the right kidney; but far exceeded the normal limit, descending below the crest of the ilium, and anteriorly approaching very close to the median line. It is hard, not remarkably tender, movable, but to the same extent as a floating kidney. The anterior edge smooth and somewhat like the spleen.

The patient's statement about the history of his disease can not be taken with perfect reliance, especially as to date when he first noticed the abdominal enlargement. Yet it must have existed several years. In spite of this fact and the comparatively little pain, and failure to establish that hæmaturia had ever occurred, no other diagnosis than malignant tumor of the right kidney seems to be warranted.

The circulation is necessarily impeded. Œdema of the lower extremities and ascites set in especially towards the close. The pulse varies, but is generally somewhat accelerated, though it may be abnormally slow.

The presence of a bellows murmur over the tumor has been observed, and is probably due either to excessive vascularity of its structure or to arterial compression. Its existence must not be lightly attributed to an aneurism, and the difficulties in the way of a correct interpretation of this symptom may indeed be very great, as shown by Dr. Holmes's case of pulsating cancer of the kidney (London *Lancet*, May 31, 1885).

Respiration may become difficult, especially near the close. Anæmia soon sets in and becomes extreme. Weakness, cachexia and emaciation mark the last stage, and the scene usually closes with death by asthenia.

The Irregular Form.—In this the symptoms are subject to infinite variation, but all the cases have one thing in common, viz.: more or less marked deviation from the type already described. In some there is entire absence of pain, either spontaneous or under pressure. In others hæmaturia never occurs, no matter how well-defined the tumor may be. In other cases hæmaturia is accompanied by severe paroxysms of pain resembling nephritic colic, as observed by Bence-Jones (*Trans. Path. Soc. Lond.*, 1875). Again, death has been known to occur without any appreciable tumor having developed during the whole course of the disease.

Complications.—These are not only numerous and varied, but often of such nature as to obscure and render difficult a diagnosis. The renal tumor sometimes compresses the bowel, so as to give rise to obstinate constipation. Pressure upon the duodenum may cause troublesome and obstinate nausea, and in a case published by Rayer perforation of the duodenum had ensued.

Pressure by an enlarged right kidney may produce jaundice by compression, and more or less complete occlusion of the biliary ducts. A case was reported in Gerhard's "*Handbuch der Kinder-Krankheiten*," and is quoted by Patino Luna, in which cancer of

the right kidney was followed by occlusion of the common bile duct, and resulted in chronic jaundice.

Ascites rarely occurs, but it was present in one of my own cases. If considerable, it may prevent a correct diagnosis. This happened in a case quoted by Luna,¹ in which the peritoneal effusion was almost the only symptom, and a cancer of the left kidney was not recognized until after the patient's death.

In a case observed by Mr. Cornil, and recorded in the memoirs of the Paris Academy of Medicine, 1865-66, cancer of the left kidney had produced complete paraplegia, with anæsthesia, and abolition of reflex movements.

Abele reported a case of renal cancer in which adhesion to the abdominal wall was followed by perforation through which a loop of intestine protruded. (Schmidt's *Jahrbuch*, T. V., p. 379, 1836.)

Radiating pains in the course of the intercostal, lumbar, crural and sciatic nerves are mentioned as not rare in renal cancer, and are explained by direct or indirect compression by the renal tumor upon the nerve trunks.

Inflammation, not only of the cancerous kidney, but of its fellow, has frequently been observed. And pyelitis and inflammation of the ureters have also been known as complications.

The supervention of intense peritonitis has been noted, due either to the irritating presence of the neoplasm, or to hæmorrhage into the peritoneum. Dr. Armand Siredey has recorded the history of a woman 53 years of age, with carcinoma of the right kidney, and of the brain, in whom hemiplegia supervened some time before death.

Diagnosis.—The published errors in diagnosis with regard to cancer of the kidney, render it more than probable that many others have been committed which have never been discovered or divulged. To enumerate even a few of the mistakes which have been recorded would extend this paper beyond its due limits. Nothing could more forcibly illustrate the difficulties so frequently hedging around a diagnosis of this lesion, nor would I desire a better justification for having invited your attention to the subject.

Among the conditions between which a differentiation of renal cancer must be made, and with which it is known to have been confounded, are, cancer of the stomach. That under certain circumstances renal cancer and cancer of the stomach may present a strange clinical similarity, is demonstrated by the fact that cancer of the stomach has been mistaken for cancer of the kidney (M. Chesnel, *Hôsp. Necker*, 1884), and that cancer of the kidney has been mistaken for cancer of the stomach (Mallassez, *Soc. Anat.*, Paris, 1870). This error would be most likely to occur when, owing to increased weight and bulk, a gastric cancer drags down the organ so as to place the pylorus considerably nearer the location of the kidneys than is common. The opposite mistake would be possible only where a renal cancer gives rise to excessive nausea and vomiting, so as to obscure the renal, and attract undue attention to the gastric symptoms.

¹ Loc. cit.

Attention to the following points will generally establish the differential diagnosis:

CANCER OF STOMACH.	CANCER OF KIDNEY.
1. Vomiting is the rule.	1. Generally absent.
2. Hæmatemesis, especially in the form of 'coffee grounds,' very common.	2. Very rare.
3. Hæmaturia absent.	3. Hæmaturia generally present.
4. Tumor in epigastrium.	4. In one or the other flank.
5. Tumor small.	5. Tumor often large.
6. Tumor movable.	6. Generally fixed.
7. Tumor descends with diaphragm.	7. Does not descend with diaphragm.

Enlargement of spleen and renal cancer have been confounded (Luna). It is, of course, only when the left kidney is involved that such a mistake is likely to be made. The two differ as follows:

ENLARGEMENT OF SPLEEN.	RENAL CANCER.
1. Absence of descending colon in front of tumor.	1. Descending colon may be found in front vertically dividing the tumor in two lateral halves.
2. Border of tumor thin, rigid, smooth, but not rounded.	2. Border often irregular, nodulated, rounded, not thin.
3. Extends upwards under the ribs.	3. Less so.
4. Direction of tumor downwards and inwards.	4. Downwards toward iliac fossa.
5. Very movable.	5. Generally almost or quite immovable.
6. History of malaria or leucocythemia.	6. Absent.

Hydro-nephrosis and renal cancer also present certain resemblances and dissimilarities, which are brought out in the subjoined table:

RENAL CANCER.	HYDRO-NEPHROSIS.
1. Generally unilateral.	1. Generally unilateral.
2. Tumor hard or irregularly soft.	2. Soft.
3. Rarely, and then imperfectly, fluctuating.	3. Fluctuating.
4. Tumor permanent.	4. Liable to subside suddenly at times, with copious discharge of urine.
5. Tumor often of enormous size.	5. Not so.
6. Tumor generally fixed.	6. Moveable.
7. Does not descend with diaphragm.	7. Descends with diaphragm.
8. Tumor of rapid growth.	8. More slow.
9. Cachexia.	9. Absent.

The differential diagnosis between cystic degeneration and cancer of the kidney is established by attention to the following points:

CYSTIC DEGENERATION.	CANCER.
1. Bilateral.	1. Generally unilateral.
2. Tumor may be large.	2. Tumor attains an enormous size, much larger than is ever reached in cystic degeneration.
3. Tumor movable; it rises and falls with the diaphragm.	3. Tumor stationary, and does not move with diaphragm.
4. Runs a rather slow course.	4. Runs a more rapid course.
5. No cachexia.	5. Cachexia sets in early, and is well marked.

Various uterine and ovarian enlargements have been confounded with renal cancer.

Malherbe (Soc. Anat., 1872) relates a case in which cancer of the kidney was mistaken for a fibrous tumor of the uterus. And Dr. Greenhalgh (St. Barthol. Hosp. Rep., Vol. 85) gives the history of a patient in whom a tumor, supposed to be ovarian, acted as a complication in two pregnancies, and the propriety of removal was about to be entertained when the patient again became pregnant. She died without obvious cause three weeks after delivery at the full term, and the autopsy showed that the supposed ovarian tumor was really the left kidney in a very advanced stage of disease. It weighed twenty-seven pounds three ounces. Pregnancy and renal cancer were mistaken for one another when foetal diagnosis was not so well understood and practiced as it is now, but at the present such an error could hardly be made or adhered to for any length of time by an intelligent and careful observer.

Besides the case of Lossen, which will be mentioned further on, it happened to Peaslee, of New York, and to Spiegelberg, of Breslau, to make the diagnosis of ovarian tumor, and to open the abdomen, when the disease proved to be renal cancer. Both patients died within three days.

The points involved in the differentiation between the two conditions are:

RENAL CANCER.	OVARIAN TUMOR.
1. Generally unilateral.	1. Generally unilateral.
2. Develops from above.	2. Develops from below.
3. Tumor hard.	3. Soft.
4. Rarely fluctuating.	4. Generally fluctuating.
5. Irregular, nodulated.	5. Generally smooth.
6. Loop of intestines in front of tumor common. Dulness to the outside.	6. Intestines pushed aside, resonance on outside. Dulness central.
7. Aspiration brings pure blood and sometimes cancerous material at point of needle.	7. Aspiration brings away characteristic ovarian fluid.

Hepatic and renal tumors have not seldom been confounded. Rayer and Frerichs both mention cases in which renal cancer had been pronounced cancer of the liver. It is true the two may coexist, as was observed in one of my own patients; but as a rule attention to the following points will distinguish them:

Cancer of the liver lies much higher and generally presents an irregular nodulated border running more or less diagonally across the abdomen; the intestines never lie in front of it. Jaundice is common, hæmaturia is rare. In renal cancer the tumor occupies a lower point, rises vertically and not so high; ascending colon generally lies in front of it. There is an appreciable interspace between the margin of the liver and the upper border of the renal tumor. Jaundice is very rare and hæmaturia common.

Many other diseases from which renal cancer is to be diagnosticated can be mentioned only in passing. Hydatids of kidney, perinephritis, psoas-abscess, enlargement of mesenteric glands, abdominal aneurism, ascites, distension of cæcum and ascending colon, etc.

The judicious employment of purgatives to empty

the bowel, the practice of auscultation and percussion, the use of the aspirator and attention to the history of the case, will generally suffice for a correct apprehension of the nature of the disease.

Duration and Course.—The impossibility of ascertaining the period when morbid processes in internal organs first begin, makes it equally impossible to designate with precision their duration. The insidious development which oftentimes characterizes cancerous disease of the kidney still more increases the difficulty, so far as this latter is concerned.

That renal cancer is in most instances unilateral, may in part account for the fact that it runs a more slow course than malignant disease of any other internal organ.

In children it is more rapid, the average duration in them being about seven or eight months.

In adults the average duration has been estimated at two and a half years, but this period has been so greatly exceeded in well authenticated cases, that one must necessarily maintain a prudent reserve when speaking of the possible duration of this disease in individual patients. Roberts has recorded cases in which the disease lasted four, six and seven years, respectively, and Jaccoud relates a case which did not last less than seven years. In some instances the fatal termination has been reached in five weeks.

Termination.—This, in most cases, takes place by gradual exhaustion from cachexia, or repeated hæmorrhages. Bright mentions a patient in whom death speedily followed rupture of a cancer, with hæmorrhage into the peritoneum. In some instances acute peritonitis has ushered in a fatal result.

Intercurrent inflammation of the kidneys, or of other organs, viz., the lungs, has been the immediate cause of death in some cases.

Secondary cancerous affections of other organs have not seldom determined a fatal issue. A fatal embolism has been induced either by cancerous vegetations, or by simple thrombi in the veins.

Uræmia is a possible, but very rare, mode of termination. Only two instances can be found specifically recorded. The first, by M. Butte, was a latent cancer of the left kidney (*Progrès Méd.*, 1873); the second by M. F. Colleville, carcinoma of the right kidney (*Bulletin Soc. Anat.*, January, 1883).

Treatment.—The medical treatment must, in the absence of any specific remedy, necessarily be limited to the treatment of symptoms, and the administration of palliatives. Yet even in this unpromising field the healing art is not without power to stay the ravages of a destructive disease, and to prolong and ameliorate existence.

In the treatment of malignant renal disease, surgery has achieved some very brilliant, if not always permanent victories. Removal of the kidney has now been performed so often that it must be regarded as an established operation. It is only with reference to its applicability to the relief of malignant disease of the organ that it can be considered in this place. Aside from the dangers incidental to the operation itself, and to the patient's general condition, it must be remembered that, while renal cancer is generally unilateral, yet both kidneys may be in-

involved, even when only one appears to be so. In fact, when both kidneys are affected, one is generally in a much more advanced state of disease than the other. In the *London Medical Gazette*, for February, 1847, is recorded the case of a child, thirteen months old, in whom both kidneys were the seat of encephaloid; the tumors were enormous and filled the abdominal cavity. In one of my own cases both kidneys were involved, though not in the same degree.

It is possible also that the patient may have only one kidney, and that one the seat of malignant disease. Such a case came under the observation of Dr. F. E. Manby, who published the history in the *London Lancet* for 1885. The patient had cancer of the right kidney, and there was congenital absence of the left.

While one kidney is the seat of malignant growth, the other may be otherwise diseased. Under such circumstances, the operation would only precipitate a fatal result.

In many cases the attempts at extirpation of the kidney for malignant disease have been ineffectual, and in others were speedily followed by death, either from shock, or peritonitis, or some other accident. The following cases of extirpation of the kidney for malignant disease are highly illustrative of the scope and merits of the operation. Other cases may have been published, but if so have escaped my attention. In 1877 Mr. Jessop, of Leeds, removed an encephaloid tumor of the kidney from a boy $2\frac{1}{2}$ years old. The little patient made a good recovery, but the disease returned in about eight months, and proved fatal in a few weeks. In 1878 Martin, of Berlin, removed a sarcoma of the kidney weighing 28 ounces, from a woman 53 years of age. She was out of bed on the eighth day, returned to her home on the seventeenth day, and was still alive two years later. In 1879 Lossen, of Heidelberg, performed nephrectomy upon a woman 37 years old, on account of angiosarcoma of the right kidney, which was movable, and the operator mistook it for an ovarian tumor. In six weeks she had entirely recovered, and remained in good health up to eighteen months later. In 1881 Czerny removed a large vascular sarcoma of the kidney from a man 53 years of age. In two months he left the hospital perfectly restored to health. At the time of operation he was cachectic, and suffered from constant nausea.

In 1883 T. Gaillard Thomas published in the *New York Medical Journal*, a case in which there was complete destruction of the kidney from malignant disease, and where he successfully effected a removal of the morbid mass by operation. In 1884, Jas. R. Chadwick, of Boston, extirpated a retro-renal sarcoma by abdominal section. In 1885 R. J. Godlee successfully removed a tumor of the right kidney in an infant by abdominal incision. It is likely that it was malignant, as it recurred after a time, and caused death. (*Trans. Clin. Soc. London*, 1885.)

THE EFFECTS OF CERTAIN PHILOSOPHICAL PRINCIPLES THAT HAVE NOT BEEN NOTICED, IN AID OF THE CIRCULATION OF THE BLOOD.¹

BY FREDERICK N. HUSTON, M.D.,
OF ROCKLAND, ME.

I assume that the subject of the circulation of the blood is not so well understood in the minds of the best scholars and physiologists, that light from a source that has no great pretensions to study and investigation would not be acceptable. I propose to treat the subject in the light of certain philosophical principles, self-evident facts that need no demonstration from experiment. I need not recapitulate all that is known and believed in relation to the circulation of the blood.

I commence with the subject of *cohesion*. "Blood has greater cohesion than water." This expression is used² in reference to the increase of friction caused by the increased area of the walls in the branches of an artery. I claim there is no difference in the cohesion of liquids. Cohesion is a peculiar property of all liquids, whereby they resemble the character of solids when acted upon by excentric forces. Where no body of the nature of air or gas is present in a liquid, or can reach any portion of it, and an excentric force is acting upon it at one point, it will act upon the entire volume of the liquid as it would upon a solid body. This fact is unscientifically illustrated by a yoke of oxen hitched to one end of a log and dragging the whole body. And further, I believe, it opens the way to a new investigation of the forces employed in the circulation of the blood. The venous system of vessels is compared by some writers to a *cone*, with its apex at the heart and its base represented by the periphery of the body. It would be quite as proper to say that its base is connected with that of another *cone* similarly representing the vessels of the arterial system.

Let us suppose for a moment that the excentric force (call it a suction force or any other), at the apex of the first *cone*, be just what is stated by the best physiologists of the day; while the ventricular systole acts like a force-pump at the apex of the second cone. It is no doubt true that friction offers an increasing resistance to the arterial current, as is stated by all writers. In the branches of an artery resistance from friction increases in a ratio with the increased area of their collective walls—the united calibre of the capillaries being 700 times greater than that of the aorta. Considering this increased resistance from friction, in the branches of an artery, while no backward flow takes place from its recoil, philosophy would teach us that the arterial wave could not fall as rapidly as it does in the trunk, unless some other physical force, strong enough to overcome the increased resistance in the branches, were acting at the same instant. Such a force could only act at the apex of the *venous cone*, or at the heart, and produce such effects upon the arterial wave.

It might be supposed that such a force at that point, which some would call a *suction force*, would not only cause the arterial wave to subside suddenly, but produce a fall or collapse of the flaccid walls of the veins at the same instant. This would not be possible. Remembering the law of cohesion, whereby liquids are acted upon in this way, as if they were solids, and recalling what has been stated and is well known of the increased resistance from friction in the multiplying branches of the arterial system, and *applying a rule that should work both ways*,—to the decreasing wall surface or area of the venous cone, it is self-evident and plain that the force at the apex, being the same to the square inch in the collective branches, while the resistance from friction is diminished in the trunks, would produce an intra-vascular pressure throughout the venous system, that would prevent collapse from outside atmospheric pressure. To illustrate this point: Suppose the suction hose of a fire engine were constructed something after the form of the *venous cone*, then, provided that the status were the same as that required for the effect of cohesion (a compact mass of water without the presence of air), the firm stiff walls required by present use to resist outside pressure would not be necessary.

This leads me to say something about cohesion in connection with the so-called suction pump, before continuing my subject. The question is supposed to have been settled by philosophers in favor of atmospheric pressure. If the cylinder of a pump contains a compact mass of liquid (as water) and no air can pass the piston while rising (if that be possible, as it must be in the force pumps of steam engines into which air is purposely admitted), the liquid is raised by cohesion and the force employed. If air be present, or passes the piston while rising (an isolated body of air, large enough to expand and occupy the area of the cylinder at one point), the liquid is raised by the atmospheric pressure, and only to the height that will balance the atmospheric column. The syphon also illustrates the effects or the power of cohesion in raising liquids. If the liquid in the syphon be a compact mass, the force of gravity in the long arm acting through the principle of cohesion, will raise the liquid in the short arm to the height of the apex and above that which would be supported by atmospheric pressure. But if there be an air bubble at the apex of the syphon, the liquid will be raised in the short arm by atmospheric pressure, and only so far as the pressure will support it.

Continuing my subject after this digression, I take up the force which I have supposed to act at the apex of the *venous cone*. The conditions about the heart, inside the chest walls, and outside of the body of the lungs must be something like that of a compact mass of liquid in the cylinder of a pump or the pipe of a syphon. There are solids and liquids, but no free air. But pressure of air in the cells of the lung might affect those conditions as it would not on the walls of a pump or syphon. The cells of the lung yield to the general expansion of the chest and the pressure of air; but at the same time there is equal air pressure upon the vessels opening into the auricles that there would be upon water entering the

¹ Read in the Section on Practical Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

² Reference Hand-Book of the Medical Sciences, 1883, vol. 1, p. 565.

cylinder of a pump. If a cavity were suddenly formed about the heart (if it were possible), at a time when the auricles were empty, and it were to be filled by the effect of outside air pressure, it seems evident that blood would be forced into the auricles for that purpose, sooner than the expansion of air in the cells of the lung could accomplish it. Besides, the outside air-pressure, through the bronchial tubes, would not be likely to reach distant cells expanding from any other cause than general expansion of the chest; so that if atmospheric pressure were alone employed in filling such a cavity, the pressure upon the vessels and their contents that open into the auricles would meet with no resistance, while the air in the cells would meet the resistance of the cell walls, besides having no power but its expansive force.

While this explanation of atmospheric pressure filling the auricles might seem possible or probable, according to accepted theories, its true value and effect is to show how atmospheric pressure may act on the circulation, while *another power* is doing the principal work. And that power is no less than the *excentric force* of the contracting ventricles—the contents of which during systole are replaced, through the property of cohesion in liquids (or liquids and solids), by those of the auricles during diastole.

Whatever other forces assist or retard this effect of the contracting ventricles, it results entirely from the law of cohesion. I have shown that the conditions inside the chest walls and outside of the body of the lungs, were such as are required for the effect of cohesion—a compact mass of liquids and solids, without the presence of free air. I have also shown the possible and probable effect of atmospheric pressure in producing or preventing diastole of the auricles. I have shown the resistance from friction, less in the venous trunks than in the collective branches; while cohesion is a property of liquids whereby they resemble solids, when acted upon by a *excentric force*. I therefore make this statement: that while no free air can reach the parts inside the chest walls and outside the body of the lungs, nor the blood in the vessels—especially those of the venous system, *each contraction of the ventricles is a force exerted with the same if not greater effect on the venous circulation, as on the arterial—not through vis-a-tergo, but through cohesion*. The blood in the ventricles is united by the cohesion of the liquids and solids outside with that which flows into the auricles, as if it were one current; and the same force which expels one from the ventricles, acting by the law of cohesion produces diastole of the auricles.

The effect of free air in the chest is well known, and the explanation of the great disturbances produced thereby is one of the many instances where Science is diffident of her own powers. How much the expansion of the air in the cells of the lung interferes with the circulation, and at the same time furnishes evidence of the truth of this theory, is shown thus: Let any gentleman present make a strong inspiration, fixing the chest in that state for a half minute—at the same time placing his finger on the radial artery. If he has never noticed the effect before, he will be surprised at the almost immediate

weakening of the pulse and perhaps its disappearance, and at its returning strength following expiration. There can be but one explanation of this result. The air cells are not only filled with air, but are fixed in that condition, whereby the effect of expansion continues to increase their capacity at each systole of the ventricles, until they act after the manner of free air in the chest—lessening but not destroying the effect of cohesion in the diastole of the auricles.

I must apologize for not noticing many important facts concerning the circulation of the blood. The time at my disposal and poor health are my excuse. I have to confess great obligations to Dr. Francis E. Hitchcock, of this city, who presents this paper to this Association, for the benefit of his experience and the aid of his friendly interest. I have not been able to assume a scientific nomenclature, such as the dignity of this subject, and this convention of physicians and surgeons have a right to expect.

But before closing I propose to notice a few points of fact and experience. "No explanation of symptoms caused by air in the blood."¹ From what I have noticed in my professional experience, in several instances where I have believed air entered the veins during hypodermic injections (the *modus* of which I will try to explain hereafter), the symptoms and sensations are the same as those experienced in a lesser degree, sometimes, during the act of vomiting when the veins are distended by muscular contractions and the fixed inspiration of the chest.

Let us suppose for a moment the effect of a globule of air (so to speak) entering a vein at the point of a hypodermic injection. Such a body of air would expand in the direction of the heart, by its own force, with that acting upon the blood in the vein, until it occupied the auricle in diastole. This appears actually to take place, from what has been learned by experiment and after death. But it would not take place if the venous blood were impelled through its channels by a *vis-a-tergo*, or muscular contraction, or by outside atmospheric pressure. The air globule would be compressed by any or all of these forces, instead of expanding into a thousand air bubbles, filling the cavities of the heart. The effect of air thus entering the vein is realized in the symptoms. The auricle is too quickly filled with rarefied air mixed with blood, in the form of air bubbles. The contracting auricle closes the superior valves, and if no air bubbles find their way into the superior vessels, intra-vascular pressure must be suddenly increased in them from other causes. The loss of cohesion by the entrance of air would take away that power, which not only aids circulation, but counteracts the effect of gravity upon the inferior vessels.

Whatever may be the effect of valves in the inferior veins, toward relieving gravity in the lower vessels, it must be remembered there is another column of blood, without valves, pressing downward with all the force of gravity, as well as that of the arterial wave. If these lower vessels, whether arteries, capillaries or veins, were compelled to sustain such a pressure it is easy to see what the effect would be.

Digitized by Google

But fortunately, the force which acts throughout the venous cone, in the direction of the heart, reaching even the arterial wave, so far unloads the inferior vessels, that the effect of gravity during the interval this force is at rest, can do no more than fill these vessels to a normal tension.

I will now explain what I believe the *modus* of air entering a vein during hypodermic injection. Some years ago I attended a patient to whom I administered hypodermic injections of morphia several times a day, for two or three weeks, during an interval of more than three years. I noticed the symptoms of air entering the circulation a considerable number of times, when the unusual bleeding that invariably occurred convinced me that I had punctured a vein. Making the injections very slowly, I believed I avoided those unpleasant effects, so that they did not occur as frequently as before. Within the past year I have attended a similar case, and have often noticed similar effects, when I have believed that I had punctured a vein. During the past four months, I have tried the expedient of making the injection while the patient held his chest at full inspiration—making the injection slowly as before—and in more than 300 injections of the contents of a full syringe, have not once noticed the unpleasant effects, that I have known to occur twice on the same day previously when I had used great care to avoid them. I do not claim this statement as authority until further trial.

The explanation I offer for employing this expedient is the following: I believed that when the air cells were fixed in inspiration, their contents would expand, and after the manner of free air in the chest, would weaken the excentric force exerted upon the venous cone, as it has been seen they do the concentric force, or pulse wave exerted upon the arteries; and hence there would not be so great a force to induce the entering of air into a punctured vein.

I will next try to show how I believe air may enter the circulation during a hypodermic injection. The fact that it does, while the syringe contains no air, cannot be denied, or at least the symptoms, that cannot be explained by a liquid entering the vein. Suppose that a vein has been punctured by the needle, and the connective tissue about it is firm and unyielding. Suppose the injection to be made rapidly, so that the skin is distended and dilated around the needle—then if the force of the contracting ventricle is acting through the principle of cohesion upon the contents of the punctured vein, it is not difficult to understand how air (in very small bulk, fortunately) may be sucked in, as it is usually expressed, through the slightly dilated tissue about the needle, as has happened in wounds and venesection at the neck.

While the skin is sustained by the liquid injected beneath it, and the walls of the vein sustained by intra-vascular pressure, as they are until cohesion is destroyed, the puncture made by the needle through these tissues is analogous to one made through the cylinder-wall of a pump.

The limits of this paper allow but a brief notice of the subject of venesection. Suppose a vein in the arm

is to be opened, and a ligature has been applied in the usual manner. The force acting upon the venous system through cohesion is not lessened in the veins below the ligature, although the current or flow is diminished at that point. It is owing to these conditions that the veins below become greatly distended, receiving more blood than the ligature above will permit to flow through the narrowed lumen of their trunks. These veins are distended, not suddenly, as from loss of cohesion and the effect of gravity, but slowly; hence the sensations and symptoms are of correspondingly mild effect. Suppose the vein to be opened. The valves in the collateral vessels will be closed at each systole of the ventricle and corresponding diastole of the auricle. They open during the systole of the auricle, through the effect of intra-vascular pressure; and the regular flow of blood at the opening is due to the contractile force of the distended vessels, that receive their supply, at successive intervals, from the choked and over-filled veins of the collateral circulation. This explanation may not seem clear without illustration, but I believe it will bear the test of philosophical criticism.

If the ligature be removed before the opening is closed, the vein above is quickly emptied of its contents by excentric force and cohesion of the blood, and is closed to the entrance of air below, by outside air pressure. But, unfortunately, this result is not always prevented by outside air pressure, as in those cases where air has entered an opening at the jugular. It may have occurred oftener in amputations than it has, but for the fact that the heart's action is greatly weakened by the shock of operation.

I will close with a brief notice of the sounds and impulse of the heart. If an *excentric force* is acting upon the venous cone, as I have described it, the blood must enter the auricles (especially the right) with some force of *momentum*. We are all familiar with the sound and shock produced by the momentum of water in a pipe, when the cock has been suddenly turned, and the stream shut off. The sound is suggestive of the first sound of the heart; and the thrill and jar received by the pipe is suggestive of that received by the chest, when the heart is in violent action. The two sounds are different and distinctive; and yet there is a similarity, as if they proceeded from a similar cause. I believe, then, that the momentum of the blood, as it fills the auricles (especially the right), and while its current is stopped for an instant, furnishes the first sound of the heart, as well as the impulse that may be felt at different parts of the chest, according to the position of the body, in some cases of enlargement of the heart. Probably I shall not find any to disagree with me, when I say that I believe the second sound proceeds from the momentum backward of the arterial blood, due to the recoil of the arteries and the closure of the valves at the heart. It is no backward flow of the arterial blood (in a strict sense) which causes a backward momentum; but the recoiling arteries, that shorten during the systole, lengthen during their recoil. This would produce a slight shock of momentum and a sound similar to the first, shorter and in a different key.

TREATMENT OF CONSTIPATION.¹

BY HENRY M. FIELD, M.D.,

OF BOSTON, MASS.

The physiological resources—or, better still, the resources answering to physiological indication—which the physician has at his command for the relief and cure of chronic constipation, may, for purposes of analysis and classification, be referred to three subdivisions.

First.—Chronic constipation is quite often habitual constipation, and is to be most effectually combated by habitual and systematic attention to the demands of nature in a periodic evacuation of the bowels. Success along this line involves exceptional intelligence, and resolution, and confidence, on the part of the patient. The poet Cowper has well expressed the difference of task in the formation of a habit and reformation in the stanza—

“Habits are soon assumed; but when we strive
To strip them, ’tis being flayed alive!”

It is far easier to swallow an occasional or a frequent pill than it is to adopt the system required for the removal of a bad habit in respect of constipation; and the patient, whose interest and confidence can be enlisted at first, too often loses faith in herself or the system, and, indeed, in the doctor. The young woman who has been so badly trained in her maternal home—and cases of this kind, throughout our best families even, are innumerable—that she has no other notion of the natural functions of the bowels than that response is to be made only to an emphatic call, an experience which may happen once in three or four days, or once a week, or less often, and who receives as a new revelation the statement of her physician that there should be alvine evacuation daily, *at a regular hour*, and the most rigid system observed in this particular, has no light occupation before her in an effort to inaugurate reform after so many years of inattention and irregularity. But such task has been repeatedly accomplished upon the condition of a fairly good constitution, of certain measures chiefly dietetic and hygienic of help, and of determined perseverance; and constipation thus cured is effectually and permanently cured.

The patient is to be instructed to select that hour of the day best in consonance with previous habits and least liable to interruption,* and invariably, as the hour comes round, to make an effort at stool, even though there be no solicitation and notwithstanding there should be frequent insuccess. So inevitably is man the creature of habit in every realm of his being, that the patient who invariably and resolutely attempts to perform any physiological function at a stated hour every day, will very surely, after a time, carry out his purpose; and the more especially in the present instance if he have every assist-

ance from a carefully adapted regimen. Of course, any physiological law whatever must have intelligent interpretation; and allowance must be made for occasional departure from the usual standard. There are patients who have excellent health upon the basis of a regular movement of the bowels once in forty-eight hours; and my preceptor, Dr. Peaslee, used to report the case, observed in one of his families, where both husband and wife, then arrived at old age, had each been accustomed for many years, if not through life, to evacuate the bowels only once in nine days! It is the principle of regularity that is to be insisted upon; and a single occasion of failure or neglect, in an individual whose bad habit of constipation had been largely corrected, may cause a serious relapse into the old and depraved method, or lack of method, of life.

Details can hardly be expected from a paper which is confessedly but fragmentary and suggestive; it is to be understood that the *regimen* which is to assist the patient in the formation of a new habit, shall receive the largest construction and be the object of a special application in every case. Whatever best offers assistance, whether from the department of hygiene or dietetics, is to be laid under contribution. Such appliances as the electric battery, the electric belt, localized massage, kneading of the bowels, etc., have a high and, indeed, an essential value in some instances.

But all cases of habitual constipation, as already intimated, are not susceptible of cure by the scheme of the formation of a new and correct habit; and this for various reasons; probably those cured and capable of cure, at least as found in adult life, are quite exceptional. The patient cannot and will not persevere in the necessary effort; the bowels, long unused to overdistension and torpor, will not respond to the most positive of alimentive stimuli; help must be had from medicine, and this medicine drawn from the class of cathartics. What is a cathartic? I have frequently found occasion to say that the definition of anything pertaining to special therapeutics must squarely meet three conditions, if it is to be depended upon to convey the requisite information: It must be intelligible and concise and comprehensive. Judged by such standard, I know not where in any of all the books devoted to therapeutics, we shall find a satisfactory definition of cathartic. Fothergill approaches the requirement of the case, and yet his terms are not quite free from fault. The following, therefore, is proposed for approval or criticism: A cathartic is an agent or agency which increases both peristalsis and intestinal secretion—either element of action, ordinarily, being prominent according to the material used—with result of provoking preternaturally free and frequent evacuation of the bowels.

There is no need to remind you of recent physiological experiments which have established the fact that every agent which acts cathartically, even though the influence be of that mild degree recognized as laxative, does so by procuring both hypersecretive and increase of contractility. One agent acts chiefly on the glandular structure and the stools will be watery; another acts mostly through energized per-

¹ Read before the Gynecological Society of Boston, May 30, 1886.

* NOTE.—*The hour best in consonance with previous habits, etc.* Not necessarily at early morning hour, although such is doubtless the hour observed by the majority of those who have established a habit of regularity. A short-sighted effort to force a particular hour upon a patient, who had individual reasons for the selection of some other period of the day, has been sufficient to bring discouragement and failure in some instances known to the writer.

istalsis, and the dejections are feculent, as with Epsom salts in the former case, and senna and aloes in the latter. There is one purgative, and perhaps only one, catharsis from which appears to present equivalent of action, viz., castor oil; a consideration which, together with the conjoined fact of nearly equable distribution of influence throughout the entire intestinal tract, renders this offensive medicament too often essential to the physician. With an occasional laxative in an occasional subject, energized contractility may be so little pronounced that the serous effusion evoked may remain in the bowel—unless reabsorbed—until some peristaltic is administered to procure its evacuation. But none the less is it true physiologically that the two elements specified always inhere to cathartic medication, and, in variable degrees, are always present in the operation of a cathartic remedy; and the recognition of this principle is essential to the successful employment of this class of materials.

Again, cathartics vary materially in their action regionally considered; *e. g.*, senna acts chiefly on the small intestines and aloes on the lower bowel. Some, like jalap, and especially elaterium, act so high up as, frequently, to involve the stomach in the irritation produced and occasion nausea, and even vomiting. It should be borne in mind that the selection of a cathartic, with respect of its operation cathartically upon the small or the large bowels, must have a very important bearing upon the alimentation and nutrition of the patient; for a cathartic which acts energetically upon the upper bowel and so sweeps it of nutritive material upon which the energies of digestion have been already expended, and which is *in situ* and in process of and for assimilation, depresses the patient far more seriously than does the emetic, which simply evacuates the stomach of undigested or indigestible food; while, *per contra*, the other purgative, which gives its force only to the larger bowel, can bring away little more than residual and excrementitious matter.

Still another fact must receive the attention of the physician who expects to employ a cathartic safely and effectively. Some purgative materials exert an influence, near or remote as concerns other organs, of which it is not practicable to take account in any definition of catharsis. In addition to modified action in the function of muscular and glandular structures, rhubarb and magnesia, prominently, effect important changes in the morbid condition of the mucosa of the intestine; and the fact that mercury is indicated in certain functional disturbances of the liver, and that aloes is contraindicated in morbid lesion of the rectum and uterus—familiar to every physician—are sufficient illustrations of the principle which we would emphasize.

Each subject of chronic constipation, requiring help from cathartic medication, must be regarded as a special problem, and, as it were, to be carefully solved before effectual aid can be afforded. An attempt to apply the methods of a routine practice will quite surely bring disaster or disappointment. The physiological characteristics of the prominent cathartics being already understood, it is now to be

determined what are the individual peculiarities of the patient who presents himself for treatment. Is the constipation to be traced to inertia of muscle? and is this located chiefly in the large or small bowel? Or, again, is the prominent defect referable to a generally defective secretion from the glandular apparatus, or perhaps the entire canal? If it is that great gland, the liver, without the normal working of which no important task of either stomach or bowels can be healthily performed, if it is the liver that is at fault, it should go without the saying that no therapeutic measures directed against constipation can be really remedial which do not ensure the return of the bile, in proper quantity and quality, to the intestine. The researches of Rutherford, in particular, among recent physiologists, have provided us with new materials for service in this direction; but all the negative conclusions of all the physiologists from the time of Bennett have not availed to release the clinical physician from primary, if not inevitable, dependence upon mercury, in all conditions which unmistakably indicate recourse to a cholagogue.

If it is a weak and anæmic woman, whose symptoms point to torpor located in the small intestine, it will be a difficult task so to adjust medication as to restore activity, procure systematic evacuation and yet not seriously to deplete. On the other hand, the individual who habitually over-eats and who is consequently plethoric and perhaps bilious and constipated, will, in addition to a timely mercurial, find an admirable resource in the frequent use of the mildly saline cathartic waters, such as hunyadi, etc., so popular now-a-days; popular, doubtless, because their special rôle has come to be so generally recognized by the large class requiring such intervention. At the same time, it may be questioned whether the practice of the Roman epicure, in the employment of the emetic, as Seneca gives it—"They vomited that they might eat, and they eat that they might vomit," was not more physiological, as it was surely more direct in its purpose and results.

Probably no one material belonging strictly to the class of purgatives is so valuably to the physician, in the treatment of chronic constipation, as is *nux vomica*, classified elsewhere; and because whatever other element may be present, a deficient tonicity is quite sure to complicate the worst cases of this affection. *Nux vomica* is the great neurotic energizer of digestion; it is to the nervous element in digestion what pepsin is as a catalytic, and it is the great peristaltic. Many cases can be successfully treated without help of other medicine than *nux vom.*, through dependence upon the measures specified in the first section of this paper. Still further, the consideration that *nux vom.* has much of the stomachic properties of the simple bitter, combined with the component power of quinia, renders it the more valuable in such application. Again, *nux vom.* is valuable because the energy for specifically peristaltic cathartic is much enhanced by its combination; so that, *e. g.*, the fraction of a grain of aloes may prove as effective in union with *nux vom.* as would a large integral dose of aloes alone.

Once more, the elimination, by the pharmaceutical

chemist, of the active principles of aloes is a fact of much importance in the treatment of habitual constipation; so far, at least, as aloetics are applicable. Thereby much greater concentration is secured, and not this alone, but the essential oil, which is largely responsible for the nauseous smell and taste of aloes, is avoided, and it is no longer obligatory upon the physician, in his offer of a purgative, to present a bulky and offensive medicament. A parvule constituted of aloin and nux vomica, aa gr. $\frac{1}{3}$; or of aloin, gr. $\frac{1}{3}$, strychnia sulphate, gr. $\frac{1}{10}$, with addition of gr. i ex j hyoscyamus, to be taken after meals once or thrice daily *pr. r. n.*, provides a resource more generally appropriate than perhaps any other that can be devised.

But aloetics have a wide and varied range of contraindication; it is pretty surely true, notwithstanding the assertion of some authorities to the contrary, that habitual dependence upon the smallest dose of aloes will gravely increase any active disease of either rectum or uterus. For the subject of chronic constipation, with complicating hæmorrhoids or metrorrhagia, or uterine inflammation, it is a difficult thing to find a substitute for the aloetic pill. But the introduction of cascara sagrada has rendered the task easier, and a pill made of nux vom. with gr. i-ij ext. cascara sagrada will sometimes meet the latter indication admirably.

It is an accepted statement with the therapeutic physiologist that physostigma increases secretion along the course of the alimentary canal; and physiologically considered, there should be provided a mild laxative in a combination of nux vomica and physostigma, as setting in active operation the two essential factors of a cathartic influence. At all events, physostigma introduced into the aperient pill should meet a corresponding indication, as respects the glandular structure of the bowel, with nux vom. in its action upon the muscular coat. From my own limited clinical experience with the former remedy, I have failed thus far to be satisfied of this fact, but in the subject of chronic constipation with prevalently dry dejections, it would receive the sanction of the authorities to combine a fraction of a grain of physostigma with the ingredient of the aperient pill.

Finally, idiosyncrasy is the occasion of much concern in the systematic and habitual use of cathartic remedies;—it is doubtful if individual peculiarities assert themselves more arbitrarily in reference to neurotic remedies than in such employment of cathartics. If the patient is a female, and especially if she has been long pampered by habits of self-indulgence and luxurious living, the case must be very carefully studied upon its own merits and demerits, or the physician will quite surely go wrong. The selection of remedies having been made and their apportionment decided upon, it is well that the patient should understand that no two cases of constipation ever required exactly the same treatment, and that quite likely there must be repeated trial and modification of the measure proposed and report to the physician before an exact adaptation can be made in the present instance. Large experience does not always bring confidence; a large experience in the treatment of

chronic constipation rather brings distrust, *i. e.*, to the physician; and it is right that the patient should, at the start, be imbued with a measure of this distrust and acquainted with the reasons for it, alike in justice to the doctor, the system and himself. Many patients will not meet the inevitable conditions—they soon get discouraged or are satisfied with partial results; but when the physician can secure such co-operation, it is assuredly alone his fault if the treatment is not at last reduced to successful terms.

There are, however, some general facts in the employment of special cathartic materials, of which the following must serve as illustrations; and the more of such the practitioner may have at command the less often will he commit a deplorable error:

1. The salines do not commonly agree with the aged—they find them too chilling; and a dose of Epsom salts, which may operate very kindly upon the young and middle-aged and vigorous, may bring serious disaster to the old man or old woman. A sudden depression of vital energy and the function of calorification thus procured, together with other favoring circumstances, have more than once precipitated the subject into a fatal pneumonia.

2. All cathartics are apt to be attended with colicky complications when given to a woman at the epoch of menopause; and especial combination at such time, as with comminatives, should be directed against this painful action. Some of the text-books or lectures used to report the case of a young doctor who was dismissed with contumely from a prominent family, upon which he had chiefly depended for the advance of his fortune, because, of offense given to the alimentary canal of a matron, through neglect of this precaution.

3. The common domestic cathartic, senna, should never be prescribed to the subject of cumulative constipation or of impacted fæces; if there be anything answerable to a fæcal plug formed in the course of the small intestine or near the valve, on either side, such a peristaltic cathartic as senna will infallibly occasion serious and even alarming colic before evacuation can be accomplished; and the same restriction applies to a similar use of an integral dose as calomel.¹

4. And to make affirmative provision for the subject of the last restriction, in a case of impacted constipation, when it is to be presumed the bowels are more or less distended with hard, dry, knotty, scybalous masses (and the more imperatively if there be suspicion of complicating typhlitis or perityphlitis), nothing works so safely and so well as Epsom salts, possibly energized with minute doses of tart. emetic, gr. $\frac{1}{8}$ to $\frac{1}{4}$. Or if it be desirable to apply a cautious peristaltic stimulant in this condition, or in whatever condition declares absence of organic contractility in the bowels, nothing else can be so direct in operation as gr. $\frac{1}{16}$ sulph. strychn., inserted once or twice in the twenty-four hours in the areolar tissue of the abdominal wall.

¹ NOTE.—An infusion of senna may, however, be administered as enema when the torpor and distension are mainly located in the large bowel, both safely and effectually. The excitant influence of senna over organic muscular fibre of bladder, and uterus also, was perhaps more familiar to physicians of an older school than to those of the present day.

5. There is apparent perplexity in providing cathartic medication, whether on occasions of temporary or habitual constipation, for the subject of a prevalent uterine hæmorrhage—*i. e.*, menorrhagia or metrorrhagia. Of course, aloetics are absolutely contraindicated, and senna and cascara no less absolutely; unless, indeed, in the exceptional instance where such a remedy as ergot is required. But there is a cathartic, or laxative cathartic, which deservedly has the reputation of exerting somewhat of inhibitory influence upon hæmorrhage from the womb, *viz.*: cream of tartar. It would be hard to name another which, in its action upon the bowels, arouses so little of peristalsis; and it is not possible that cream of tartar, in any degree of action, should stimulate uterine muscles to contraction; while its tendency to reduce temperature, and especially to lower blood pressure, should work favorably for the arrest of hæmorrhage from whatever cause.

The last section of our subject contemplates, if not the cure of habitual constipation, at least an escape from its discomforts and injurious influence upon health, by the systematic use of water-enemata; but its discussion must be postponed for want of time. It may be said, however, in closing, that loose and erroneous notions prevail to an extent among the profession even, respecting the value and the consequences of this measure of relief. The rectal syringe, like the uterine pessary, may do incalculable mischief; suitably, appropriately, strictly and intelligently controlled, it may be of incalculable benefit. In either instance, there must be selection of cases and considerate adaptation. In no other department of medical practice is the tyro in medicine more out of place, as well as the physician who gives but a passing thought to the condition for which he is called to prescribe.

MEDICAL PROGRESS.

PLACENTA PRÆVIA.—At the first meeting of the German Gynecological Association Dr. BAYER, of Strassburg read a paper on this subject. Duncan's theory as regards hæmorrhages in placenta prævia was formulated to apply only to the hæmorrhages occurring with the pains and suffices for these alone. Since that time we have learned of the formation of a lower uterine segment. This is not simply the lowest portion of the uterus, but a zone, characterized by quite definite qualities, which does not take part in the contractions, and depends after labor in a condition of extreme relaxation. The hæmorrhages have been brought into connection with the development of this lower segment, and since the latter forms during pregnancy, this apparently explains also the hæmorrhages occurring during gestation. He then compared the various views respecting the origin of the lower uterine segment with the conditions existing in placenta prævia. According to the views of those who look upon the lower segment as a portion of the body of the uterus, the placenta prævia must

be partly or wholly inserted into the segment. But this is a physiological impossibility, at least in cases terminating favorably, for owing to the absence of contraction or retraction of the placental site in the lower segment, every parturient with placenta prævia would be hopelessly doomed to death from hæmorrhage. The other view, according to which the lower segment forms from the supravaginal portion, explains the phenomena in a less forced manner. But then the questions arise, why does hæmorrhage not invariably occur during pregnancy and why can the placenta be felt occasionally immediately over the closed cervical canal, or one with opened parallel walls? These objections cannot be explained by saying that the conditions vary in different cases. He concludes from the observation of twenty cases that in placenta prævia similar conditions prevail as in premature labor, that is to say, that in that condition the defective development of the supravaginal portion is a typical phenomenon; that furthermore the internal os occasionally remains closed until the actual commencement of labor, and that in that case no lower segment is formed.

Dr. Bayer distinguishes:

A. Simple low insertion of the placenta, where the margin of the placenta reaches only into the neighborhood of the internal os. Here hæmorrhage occurs only during labor, when a portion of the placenta remains in the area of relaxation, *i. e.*, when the lower segment is not formed normally. Accordingly he found low insertion of the placenta with hæmorrhage during delivery only in premature labors in the eighth or ninth month.

B. True placenta prævia. To constitute this condition, it is necessary that some portion of the placenta at some time covers the internal os. There is only a difference in degree between placenta prævia centralis and lateralis; the former may pass into the latter in the course of pregnancy or not until labor, when the supravaginal portion develops accordingly; inversely, the symptoms of placenta prævia centralis may be present, although only a small lobe projects over the internal os, when the latter did not dilate materially before the examination. As the internal os opens, the placenta inserted upon it must become detached or it must tear; in either case hæmorrhage occurs. If this takes place during pregnancy, provided the latter continues after the first hæmorrhage, we must expect alterations in the placenta. In the cases observed by him, such alterations were constant when hæmorrhage had occurred previous to labor; they were always absent when the first hæmorrhage took place at the outset of true contractions.

He distinguishes:

1. Hæmorrhages during pregnancy; they characterize cases in which the os opens during pregnancy.

a. The placenta remains firmly on its seat, while the portion on the os internum tears; the laceration may extend to the membrana chorii; in this case labor will probably set in soon or the child die from loss of blood. If the internal os opens very gradually, more superficial lesions of the placenta may arise; according to the view of the author, a placenta marginata occasionally forms by the tearing apart of

the placenta, flattening and relatively excessive spreading of the maternal surface. Perhaps such lacerations or tearing apart of the cotyledons over the internal os explain also the cases of placenta succenturiata.

b. When the internal os opens, the smaller lobe of the placenta is loosened; it falls into the lower segment which develops only to a slight degree; it becomes exsanguinated, flattens, atrophies, and detaches itself from its chorionic insertion. This form of placenta, therefore, can be looked upon as a partial placenta marginata. Should the pregnancy continue long enough after the detachment of the smaller lobe, it is possible that a lower segment of normal extent will form subsequently; if the placenta at the same time is situated at the anterior wall, it will possibly be no longer palpable during labor as prævia, and in some cases not give rise to hæmorrhage even during the pains.

2. Hæmorrhages during true contractions. Here Duncan's explanation is valid. The uterus draws itself upwards at the placenta so long as the ovum remains intact. In this way, a larger and larger portion of the placenta appears free; the lobe thus detached looks thick, saturated with blood, bluish-red, and covered with clots. If it was the source of hæmorrhage before or during pregnancy, there are besides corresponding alterations in the placenta. In rarer cases, the internal os remains closed until the onset of labor. Then there is an absence of those changes in the placenta which require time for their development, but there is also an absence of every uterine hæmorrhage during pregnancy, and the course of the labor in such cases is usually more difficult, and more dangerous for mother and child.

a. The unfolding of the cervix during the pains progresses in a normal manner. In such cases the manipulations of the attendant are rendered more or less difficult, and the ordinary cervical lacerations—longitudinal tears through the lower portion of the neck—occur more readily. The first hæmorrhage is then usually of special severity, as Spiegelberg has formerly pointed out.

Of much graver import are the cases in which the still undeveloped supravaginal portion shows a tendency to form a stricture—placenta prævia with stricture. In such cases, the internal os remains comparatively narrow during the pains, while the inferior portions of the cervix dilate in form of an ampulla. The author has met with a similar case in which the parturient lost no blood, not only during pregnancy, but even for two days during labor, although placental tissue was situated all around over the internal os. Immediately after labor, the patient bled to death from a fistulous cervical laceration extending as far as the peritoneum. He proposed the following divisions:

1. Placenta prævia with corresponding development of the supravaginal portion and hæmorrhages during pregnancy and alterations in the placenta. He observed ten cases with hæmorrhages during pregnancy; among these were two cases of placenta marginata totalis, six of partial placenta marginata, two of placenta succenturiata. Eight children were

born living, one at six months, one dead. All mothers recovered.

2. Placenta prævia with cervix remaining intact until the onset of true labor; no chronic alterations in the placenta, no uterine hæmorrhages during pregnancy. Aside from three cases of low insertion of the placenta and hæmorrhage with premature labor, he had observed seven cases of placenta prævia without hæmorrhage during pregnancy. In six of these, labor occurred at term. Two children were born living, five dead; one mother died of hæmorrhage immediately after labor, one had a severe attack of parametritis, one required the suturing of the cervix. —*American Journal of Obstetrics*, August, 1886.

SULPHATE OF IRON IN DIARRHŒA.—MR. CHARLES ROTHWELL says in the *British Medical Journal* for July 17, there is a memorandum from Dr. Braithwait, of Leeds, on the treatment of diarrhœa in children by the sulphate of iron. Although I have no experience of its efficacy in children, I can endorse the same in the choleraic diarrhœa of adults. It was during the last real invasion of our country by cholera in 1850, when East London and Gateshead suffered severely, that the valuable suggestion of treatment by the iron sulphate was adopted with success in the larger number of cases of choleraic diarrhœa, if not real cholera, treated here, such cases being diagnosed by blue, cold, wet skin, writhing cramps, and vox choleraica, which, once heard, is never forgotten. It is to be noted that Dr. Braithwaite has omitted mention of what used to be considered the "best bower anchor" in the treatment of all diarrhœas, namely, laudanum, which, if it held, only made the unfortunate vessel swing round upon rocks as dangerous as the storm itself. It is generally known that this ferric salt is, or ought to be, widely used for the disinfection or correction of decomposing fomites of disease in midden heaps, sewers, and the like. Why not use it in the aboriginal and typical sewer in *corpore vili*, in the flushing of which nature uses the most valuable of storm-waters, namely, blood-serum, *plus albumen*, to the destruction of the house that owns it? I would suggest the use of this salt by injection, in cases where persistent vomiting stops the way.

TAKING THE TEMPERATURE IN CHILDREN.—A very ingenious and simple method has been proposed by FILATOFF, in the *Archiv für Kinderheilkunde*, vol. vii, part 3, for expediting the troublesome process of obtaining the temperature in children.

He recommends that by the use of a previously warmed thermometer the fall, and not, as is usual, the rise of the mercury be observed. In from one to two minutes the column is found to stop at a point which very closely approximates to the actual temperature of the patient. It is found that the higher the fever, the smaller is the error. Thus, at temperatures of from 103.1° to 104° F., the error does not exceed 0.2° F., while for lower temperatures it may reach 0.5° F. It is, of course, evident that a certain amount of care and skill is requisite in order that the precursory warming of the thermometer be neither insufficient nor excessive. —*Med. News*, Aug. 28, '85.

SATURDAY, SEPTEMBER 11, 1886.

DIABETIC COMA.

There has been a great deal of unfruitful speculation in regard to the nature and causes of the so-called diabetic coma. It has been applied to a form of coma which occurs late in the disease, and which frequently terminates the affection, and is also used to indicate a train of nervous symptoms of which coma is the terminal one. "To this train of symptoms the word acetonæmia is also applied, and should alone be used," says Tyson, "while the term diabetic coma should be restricted to the terminal symptom." One of the most thorough reviews of this subject that has come out for some time is the Bradshaw Lecture, delivered on August 18, before the Royal College of Physicians of London, by DR. JULIUS DRESCHFELD. The lecture may be found in full in the *British Medical Journal*, of August 21, 1886. "By diabetic coma," he says, "we understand a peculiar train of symptoms coming on, more or less suddenly, in the course of diabetes, characterized chiefly by coma, and often ending fatally in a very short time." We cannot, however, hold diabetic coma responsible for every sudden death occurring in diabetes, even though coma may form a principal symptom; there may be a well-known cause for the death, and distinctive lesions may be found after death. The death may be due to cerebral hæmorrhage, or to dyspnoæic coma of acute pneumonia; or, as when a true nephritis exists with the diabetes, death may be due to uræmia.

In a paper read in 1881, before the Manchester Medical Society, Dr. Dreschfeld classified the cases of diabetic coma into three classes, according to the symptoms: one form, characterized chiefly by drowsi-

ness, soon passing into coma; a second, resembling alcoholic intoxication, a marked symptom of which is a staggering gait, incoherent speech, and an excited condition of the nervous system, followed by drowsiness and coma; and a third, including the greater number of cases, in which dyspnœa is usually a most marked symptom, followed by coma, both the breath and urine having a strong odor of acetone, and the urine containing a peculiar body giving a deep claret color with perchloride of iron. Some time after this paper was read Frerichs adopted an almost identical classification as regards symptomatology, and more clearly distinguished the pathological differences between the first group and the other two. To the first group Dr. Dreschfeld would give the name "diabetic collapse," and as regards the symptomatology we find a condition somewhat as follows: "The patient, without any premonitory symptoms, begins to suffer from drowsiness, hebetude, excessive weakness in the limbs; the extremities become cold; hands, feet, and face become livid; the pulse quick, small, threadlike, soon reaching 120 and 130; the respirations are only slightly quickened, shallow, without there being much dyspnœa; the temperature gradually falls, the skin in some cases becomes covered with perspiration, and death ensues from collapse in most cases within ten to twenty hours. During the first few hours, the patient is still able to pass urine voluntarily. With the progress of the coma the urine is retained in the bladder; but, when withdrawn, is found to contain a considerable amount of sugar (5 to 8 per cent.), but no acetone or aceto-acetic acid. In two cases which I had an opportunity of seeing, it contained a small amount of albumen. The nervous system presents few other symptoms besides the coma; the pupils react, though somewhat sluggish; there may be some slight headache, but active delirium and convulsions are mostly absent. The post-mortem examination shows no marked naked-eye changes." The data are insufficient to enable us to show how many cases of diabetic coma belong to this group; but as regards the etiological factors we may draw the following conclusions: "1. Diabetic collapse occurs chiefly, though not exclusively, in older people, after the age of 40. 2. It attacks persons who have suffered from diabetic symptoms for some time, and who are, as a rule, still stout and well-nourished at the time of attack. In short, the cases belong more to that form of diabetes recently described by Hoffman as constitutional diabetes, or diabetes of stout people, where the course of the disease is slow and protracted, and where gout or nephritis form frequent associations, and where the

appearances of carbuncles and other necrotic changes are not uncommon." Prout pointed out that the exciting cause is some extra physical exertion in the majority of cases; and in a smaller number of cases an error of diet, or immoderate drinking. As to the cause of diabetic collapse, Frerichs believed it to be due to heart-failure from fatty degeneration; a view which seems to have the strongest support. Schmitz showed that of 109 diabetic patients eighty showed considerable heart-weakness. "If death be due to sudden exhaustion brought about by a more than ordinary demand being made on the constitution weakened and altered by the diabetes, we should expect a somewhat similar mode of death in other constitutional diseases where the heart's muscle is altered and the blood has undergone changes, but where there is no diabetes; and that this is actually the case, is easy of demonstration."

The alcoholic form of diabetic coma is rare, and Dr. Dreschfeld thinks that it is most likely identical with the third class. In its symptoms it resembles acute alcoholic intoxication, and Kulz has recorded a case in which the urine contained large quantities of alcohol. Frerichs has described some cases similar in symptomatology to alcoholic intoxication, in which the expired air smelled strongly of acetone; but no mention was made of the presence of alcohol in the urine. If this class is to be regarded as a distinct pathological type it will be necessary to have more definite data as to the presence of alcohol in the urine.

"Coma from acetonæmia," the term which Dr. Dreschfeld applies to the third form, is the most common of the three classes. He has observed sixteen fatal cases, and studied the pathological changes in ten cases. In making a detailed analysis of the symptoms we find those referable to the nervous system, the vascular system, the respiratory apparatus, the digestive system, the urinary organs, the temperature, and the blood. In regard to the first there is a period of excitement, during which there are headache, vertigo, a state of excitement not unlike that of alcoholic excitement, incoherent speech, and delirium bordering on mania. Convulsions are rare, though there may be jactitation. Sooner or later these symptoms are followed by signs of depression, such as hebetude, thick speech, drowsiness and coma. The pupils may be dilated or contracted, and react almost to the last. Abdominal pain is an early symptom, and may simulate peritonitis. The vaso-motor system is much affected; the face is often flushed at first, becoming pale afterwards, and the extremities become cyanotic. The skin may be dry at first, but later may be covered with clammy

perspiration. The pulse is one of low tension, becoming quick, small, threadlike, and irregular; while the heart's action is feeble. The symptoms referable to the respiratory apparatus are marked dyspnoea, which may be one of the first symptoms, increasing to the last, inspiratory at first, and then both inspiratory and expiratory. It has been accurately described by Kussmaul, the thorax expanding well in all directions, the air, on auscultation, being heard to enter all the parts of the lungs; but in spite of this there is great breathlessness. The respirations may be increased or diminished in number. There is often a pain in the chest, and a limited pleuro-pneumonia may be sometimes found. The exhaled air has a chloroform-like smell, which is due to acetone. The symptoms referable to the digestive tract are, a dry red tongue, loss of appetite, nausea, vomiting of copious masses, and tense epigastric pain. There may be an intermittent constipation or profuse diarrhoea from the first. The urine is diminished, as well as the amount of sugar, which may entirely disappear. The urine is often very acid, but not always so, and the amount of ammonia is often increased. The urine has the peculiar odor of the breath, and contains acetone; giving the characteristic claret-red color with perchloride of iron, which is undoubtedly due to aceto-acetic acid. It may contain a large quantity of fat, and often contains albumin, from a trace to a considerable quantity. The temperature rises during the first stage, but it falls with the onset of coma, and may go down to 95°, 94°, or as low as 90°, just before death.

It may be said that diabetic coma is fatal in about 90 per cent. of the cases. Some of the cases run their course without premonitory symptoms, within from twelve to twenty-four hours, though in about 60 per cent. of the cases the duration of the attack is two or three days, and has such premonitory symptoms as lassitude, abdominal pain or dyspnoea; while in other cases the coma is preceded by several weeks or months by a condition which is known as chronic acetonæmia. After the graver symptoms of coma have appeared it is exceptional for the patient to show any improvement. In rare cases the symptoms may improve for a time, and then reappear with fatal results, or a gradual and steady improvement may take place.

Several points in the etiology of diabetic coma seem to be clearly established; it chiefly affects younger persons. Pavy found that 55.65 per cent. of the cases of diabetes occurred between the ages of 40 and 60; and from an analysis of 80 cases of diabetic coma Dreschfeld finds that 70 per cent. oc-

curred between the ages of 20 and 40, and only 24 per cent. between 40 and 60. It may occur at a much earlier age, even under 5 years. The coma may come on very early in the course of diabetes. In the younger persons it usually appears from six to twelve months after the first symptoms of diabetes; while in older persons it comes on later. It seems to occur almost exclusively in the severer forms of the disease. There are reasons for supposing that hereditary disposition may play some part in the etiology of the affection. Excessive physical exercise is the exciting cause in about 50 per cent. of the cases; mental shock about 10 per cent. Sudden change from a mixed to an exclusively nitrogenous diet is an exciting cause. Coma sometimes follows a surgical operation on a diabetic; though we cannot say whether this is due to the shock to the nervous system from the operation, or to the anæsthetic—more probably the former. It may also follow intercurrent febrile affections occurring in diabetic patients.

In any discussion of the pathology of diabetic coma we must give greater prominence to the abnormal bodies circulating in the blood and appearing in the secretions; fat in the blood, and acetone, aceto-acetic acid, and β -oxy-butyric acid. As regards the presence of fat in the blood, it will be remembered that Sanders and Hamilton put forth the ingenious but untenable theory that the symptoms of diabetic coma might be due to fat-embolism. Acetone and aceto-acetic acid are found in the majority of cases of diabetic coma. Dreschfeld has not failed to find them in any case examined since Legal's test was made known; this consists in the addition to the distilled portion of the urine of a small quantity of caustic soda solution, then a few drops of a solution of sodium nitro-prusside, and then a few drops of acetic acid, when a beautiful red color appears if acetone be present. The tests for aceto-acetic acid are as follows: 1. The urine is treated with concentrated solution of perchloride of iron, and filtered from the phosphates, which are precipitated. The claret-red color disappears on heating. 2. The urine, after the addition of a small quantity of dilute sulphuric acid, is shaken up with ether, and in the ether extract, which takes up the aceto-acetic acid, perchloride of iron produces again the characteristic color which gradually fades on standing. 3. The urine, on distillation, gives characteristic reaction for aceto-acetic acid is easily decomposed.

Have these bodies any toxic effect when administered to man? It seems that they have not, though Dreschfeld and others have tested the matter thor-

oughly. If present in the blood of animals in large quantity, and not quickly eliminated, they will produce effects similar to those of diabetic coma. Acetone and aceto-acetic acid may occur in the urine in many acute and chronic and acute diseases; and though they often cause only slight and temporary symptoms, they may give rise to the dangerous symptoms of diabetic coma (or the coma seen in diabetes). There seems to be little doubt that the functions of the kidneys and liver are seriously impaired in diabetes, even though the material changes may not be prominent; and there is reason to believe that the impairment of the hepatic functions is the more serious. "Whilst believing that acetone has a large share in the production of the symptoms, I hold that it is only one of a series of bodies of which aceto-acetic acid is another, β -oxy-butyric acid a third, and of which there are probably more, which, if not quickly eliminated, act powerfully on the nervous system, and thus produce diabetic coma. Whether some of these acids act by withdrawing the alkalies from the blood; in fact, whether they produce an acid intoxication, as Stadelmann and Minkowsky believe a statement which is supported by the experimental research of Walter on the action of acids on certain animals, remains yet to be seen." Dr. Dreschfeld compares the third form of diabetic coma to uræmia, though the toxic agents and symptoms are different. It is possible that the studies of Brieger, Bouchard and Gautier on the fermentative changes going on in the body will yet throw some light on these obscure subjects.

EMOTIONAL ICTERUS AND LICHEN.

So many cases of emotional icterus are on record that it is scarcely worth the while to enter into a statistical discussion to show the existence of such an affection. DR. NEGEL, of Jassy, Roumania, reports, in *Progrès Médical*, of August 21, a "case of emotional icterus accompanied by a general eruption of lichen," which is sufficiently rare to give in detail. The patient was 23 years old, of robust constitution, with a tendency to obesity, and for some years subject to acne of the face and back, and there was slight submaxillary engorgement. There was no hereditary taint in the patient.

In February, 1885, there was an herpetic eruption on his prepuce, which he himself treated with cauterizations of nitrate of silver, as a result of which there was an enormous ulcer and balano-posthitis. He then consulted a physician, who ordered emollient dressings, but the ulcer grew larger. To make a

long story short, the physician finally told him that his penis would gangrene; but the patient showed so much alarm that Dr Negel was consulted. When he arrived some time later, he found that the patient's urine was brown, and left a deposit in the *pot de chambre*; the faecal matters were colorless, and there was slight constipation. This state lasted for two days, when the patient noticed that his saliva was bitter, and there was slight fever. There was now intense icterus, accompanied by an eruption of lichen, situated principally on the thorax (back and sides), abdomen and face, the limbs and scrotum. It was of the simple variety, and presented a few vesicles here and there. The urine contained a great deal of bile pigment. An emeto-cathartic was given, and then saline purgatives, lemonade, bicarbonate of soda, and antiseptic dressings were applied to the ulcerated and swollen prepuce.

After ten days of treatment the ulceration and balanitis were almost cured, but the lichen persisted. The icterus had greatly diminished. After about three weeks the patient was practically well, but there was still some jaundice and lichen.

ARTIFICIAL QUININE.—*The Lancet*, of August 28, intimates that Mr. Creswell Hewett has made a discovery by which quinine may be made by synthesis, from an article which may be got in abundance in any part of the world. It is thought that Mr. Hewett will put himself in communication with the British Government, which spends \$300,000 annually in India alone in the cultivation of the cinchona tree.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Tenth Annual Session, held at Indian Harbor Hotel, Greenwich, Conn., August 25, 26, and 27.

WEDNESDAY, AUGUST 25. FIRST DAY.

MORNING SESSION.

THE PRESIDENT, DR. EDWARD WIGGLESWORTH, of Boston, delivered the

OPENING ADDRESS.

Just ten years ago, at Philadelphia, I had the honor of calling to order the first public meeting for the organization of this Association. Our specialty for the first time, received national acknowledgement. Our guerilla warfare was over and our subsequent record has been one of unbroken successive victories over bigotry, error and ignorance. But the day of Paladins is past and our ranks will admit more re-

cruits. There are still remaining opportunities for more extended instruction of students in medical schools, while the lack of hospital facilities for the proper clinical treatment of diseases of the skin, is a standing shame and disgrace to our municipal authorities, our hospital boards, and to the medical profession itself. "As now arranged nearly everywhere amongst us, these institutions refuse to a large class of sick persons, the benefit of hospital residence either wholly, or offer them, if received, not we may fairly say, the best medical skill it is in their power to procure." Some progress has, however, been made. New York has now a special hospital for skin diseases, besides two wards in the Charity Hospital, and Philadelphia has special clinics with beds at three different institutions.

About twice as many cases of diseases of the skin are now annually treated by specialists as there were ten years ago. The contributions to American Dermatological literature during the past decade, include the best treatises, hand-books and atlases, the only periodicals and some of the best monographs of the time, in the English Language.

While much has been accomplished, much still remains to be done. The idea of specialism, already rooted, is to be nurtured and trained in the minds of the profession and of the public, and the practical development socially of our specialty itself is to be elaborated in many minor details. The pioneer must no longer prove a martyr. A knowledge of the weaker side of human nature, useful for selfish financial ends, must no longer be allowed to usurp the province of exact scientific acquaintance with disease, inuring to the benefit of our race. The "elaborate division of labor" is as "useful and successful in a learned profession as it is in the mechanic arts," for it is merely a relative question of height of standard. Specialism substitutes quality for quantity, which substitution is the essential characteristic of the civilized man as distinguished from the savage, while the rapidity of such substitution, gauges the progress of civilization itself. Medicine is merely that complex whole which results from the combination of all its component parts, and their individual advancement is the criterion of its own progress.

Believing in the ultimate achievement of all possibilities and in the progress of Truth, I have no doubt as to the future of specialism if we are honest and earnest. Not infinite omniscience, but infinite morality is the duty of the specialist, and this conscientiously carried out, will blunt the sharpest dart of the hostile general practitioner. While visions of what yet remains to be accomplished might well lead us almost to despair, a mere glance at the generally prevailing ignorance on the part of both physicians and their patients, shows conclusively that we and our work are imperatively demanded.

DR. EDWARD BENNET BRONSON, of New York, read a paper which was entitled

ERYTHANTHEMA SYPHILITICUM.

Attention was called to certain cutaneous eruptions of an erythematoid character occurring in connection with syphilis, and the attempt was made to de-

termine their etiology. A case was reported of a syphilitic patient who developed a peculiar eruption upon the head, hands and feet. Although the eruption presented no pronounced syphilitic characteristics, it was regarded as due to syphilis for the reasons that it was shortly followed by an outbreak of well-marked specific efflorescences on various parts of the body, and moreover, there was a transformation of the eruption upon the head, into infiltrated lesions presenting a distinct syphilitic character. The eruption first appeared on the face in the form of an erythema which was covered with vesiculo-papular efflorescences. Later, a similar outbreak occurred on the nape of the neck. The vesiculo papules broke, leaving excoriated surfaces of a diphtheritic character from which there exuded an exceedingly abundant, foul-smelling discharge. Soon after vegetating growths made their appearance, which upon the bearded parts of the face were quite exuberant and resembled condylomata acuminata. Those upon the neck, formed more discrete, tuberos prominenances and had the appearance of condylomata lata; while upon the upper parts of the face, the elevations were nummular and had comparatively smooth, though somewhat lobulated surfaces. After a week or two, the erythematous areas, which formed the bases of the vegetating lesions, became the seats of a gradually increasing, copper-colored infiltration. The palms and corresponding surfaces of the fingers, were covered with a deep-red sharply circumscribed erythema, which was followed by lamellar desquamation. A similar eruption occurred in patches upon the soles. The finger nails were all more or less affected with onychia sicca. Upon the body and limbs, several crops of well-marked syphilitic papules succeeded each other, and finally all the manifestations yielded rapidly to mercurial treatment. The preliminary eruption in this case was characterized as an erythema dependent in some way upon the specific disease. Other instances of erythematoid eruptions occurring incidentally to syphilis, were referred to as being more or less analogous to the above cited case.

He attempted to define more precisely the etiological relations of these various erythematoid eruptions occurring in connection with and probably as a consequence of syphilis. It was maintained that probably they were not equivalent in their mode of origin to the syphilodermata, but rather to certain angioneurotic or neuritic affections, which they closely resembled. The true syphilodermata are always characterized by a specific infiltration and are probably the result of a determination of the *materies morbi* to the surface. They are therefore pathognomonic of syphilis. The erythema syphiliticum, on the other hand, is only an indirect effect of the syphilis, the result of reflex irritation of the skin from the action of the skin from the action of the disease upon nervous centres, and therefore not pathognomonic of syphilis. The fact that this might be followed by a true syphilitic infiltration *in situ*, was regarded as analogous to the effect sometimes observed of traumatic irritation in syphilitic subjects, where local injuries became the seat of specific infiltrations.

DR. I. E. ATKINSON, of Baltimore, held that with reference to pathognomonic syphilitic eruptions, a great deal of caution should be exercised. Lesions similar to those described by Dr. Bronson are not of excessive rarity in cachectic subjects and in cases of malignant syphilis, but in his experience, they have always been manifestations of late or tertiary syphilis.

DR. J. C. WHITE, of Boston, said that the diseases which had been described are so rare in syphilis, so little is known of the nature of erythema nodosum and its causes, and we know so little of the nature and causes of so-called erythema herpetiformis, that it seems to him that we must have some more exact data before we can regard these affections as a necessary sequel of syphilis, and as anything more than accidental occurrences.

DR. G. H. TILDEN, of Boston, thought that in the present state of our knowledge it would be more philosophical to consider the appearances described as accidental rather than as dependent upon the specific disease.

DR. I. E. ATKINSON, of Baltimore, read a paper on
RUBELLA OR RÖTHELN.

The paper was based upon a review of the literature of the subject and a study of the reported cases, and gave a complete account of the disease, as regards its symptoms, duration and diagnosis. On account of the confusion existing as to the nomenclature of this disease, the speaker suggested that rubella be accepted as its proper title, and that it might be known in popular language as epidemic roseola.

DR. WIGGLESWORTH said that he had suggested several years ago that measles be called morbilli, and rubella or rötheln be used to signify what is termed German measles, and roseola be reserved as the title for the rose-colored spots seen in syphilis and other conditions. There seem to be no necessity for the introduction of a new term.

DR. G. H. FOX, of New York, reported a case of
LYMPHADENOMA (MYCOSIS FONGOIDE) AND AUTOPSY.

Mrs. G., aged 33 years; the mother of six children. During pregnancy in the summer of 1881, she suffered with general pruritus, which passed away after confinement in October. A year later, small flattened circular tumors appeared in the axillæ and on the breasts. These became moist and were accompanied with a burning sensation. The eruption disappeared from these situations and reappeared upon the back and other portions of the body. After the birth of her last child in February, 1885, a tumor developed at the inferior angle of the left scapula. The lesions on the other parts of the body disappeared with the exception of two spots on the finger, and one on the left cheek. The tumor on the left scapula gradually softened and disappeared.

The patient was admitted to the hospital in October, 1885, and was fairly well nourished. There were at this time numerous tumors over the body, some of which were superficially ulcerated. The worst tumors were on the breast. Hypodermic injections of Fowler's solution were used without benefit. Chaulmooga oil was given in increasing doses

until forty drops four times daily were taken without causing any improvement.

The patient died in April, 1886. The microscopical examination gave usual appearances of these growths. The internal organs were found to be normal.

DR. G. H. TILDEN remarked that Rindfleisch states that he has found a distinct micrococcus inside of the blood vessels in this affection. Recently this has been confirmed by another observer. It looks as though what we ordinarily know as malignant lymphoma, affecting the lymphatic glands, with deposits in other parts of the body (Hodgkin's disease), is one of the infectious diseases. He thought it probable that mycosis fungoides is a variety of the same disease, and that it is nothing but an acute infectious disease.

DR. J. NEVENS HYDE, of Chicago, read a
NOTE RELATIVE TO THE BULLOUS ERUPTION OCCUR-
RING AFTER THE INJECTION OF IODINE
COMPOUNDS

(Read by the secretary).

Several illustrative cases were reported. There are two distinct types, the bullous and the quasi-bullous eruption produced by the injection of iodide of potassium. In the first form the patients are often well advanced in years, often cachectic and frequently affected with syphilis or other grave disease. In what may be regarded as a second sub-form of this exantheme, there are di- or polymorphic symptoms. Here bullæ are commingled with papules, tubercles and other patches of disease. In conclusion the author presented the following interrogative propositions:

1. Are there not three sub-forms of the bullous exantheme developed in certain individuals after the injection of iodide of potassium?
2. Is not the first and most common of these to be generally recognized in persons of advanced age and cachectic condition, the rash being then present in the form of typical bullæ?
3. Is there a second and still rarer sub-form, in which the eruption is displayed in di- or polymorphic manifestations, typical, perfect bullæ being then mingled with papules, tubercles, scarlatiniform maculations or with other and different lesions?
4. Is there not a third and rarer sub-form, the quasi-bullous rash to be most frequently recognized on the face and dorsal aspect of the hands and forearms of infants and children, where the lesions are semi-solid, slightly umbilicated and filled with inspissated yellowish matter, and which may shrivel and desiccate on the suspension of the drug inducing the condition?
5. Is this last described lesion one to be recognized solely as the result of the injection of iodide of potassium, never under other circumstances, and one as peculiar to the special condition it represents as is the gumma to syphilis?

DR. R. W. TAYLOR, of New York, reported a case of a peculiar form of iodic poisoning. It was in a case of gummatous infiltration of the pharynx where iodoform had been resorted to as a local application. In the course of two hours it produced a diffuse eruption on the face, neck and hands. On the hands, it assumed an eczematous character.

DR. J. E. GRAHAM, of Toronto, described the case of a young man 22 years of age, had contracted syphilis two years previously. Noticing some pimples on his face he secured a preparation of iodide of potassium containing 5 grains to the dose. Two days later after he had a bullous eruption, principally upon the face and neck. Thinking this was a tertiary manifestation the dose was increased to 15 grains. Two days later, the eruption on the face was much increased, and recognizing the cause of the condition, the remedy was stopped and the eruption rapidly disappeared.

DR. ATKINSON referred to a case of what was supposed to be malignant syphilis, the patient had had syphilis, and had been put on the use of iodide of potassium. The lesions continued to increase, and after the iodide had been taken for six months, Dr. A. saw the case. There was an enormous formation of scar-tissue over the face and neck. In addition there were bullæ and elevated infiltrated plaques. The drug was stopped and in six weeks the ulcerations had healed, the cicatricial tissue of course remaining.

EVENING SESSION.

DR. R. W. TAYLOR, of New York, read a paper on
PRECOCIOUS GUMMATA.

Of the precocious gummatous syphilide or gummata there are three quite clearly marked forms: *First*, the early, general and copious form; *secondly*, the more localized form, which may invade several regions and is usually symmetrically distributed; and *thirdly*, a form in which more or less severe neuralgias precede and accompany the eruption, which in many particulars resembles simple erythema nodosum, but which in its etiology is not in any way related to this simple form of eruption, but is a direct outcome of the syphilitic diathesis. These precocious gummata partake in general of the features of those of later forms, but they differ in a more acute invasion, in a much more rapid course, and are usually not as destructive in their action as the classical eruption. In the treatment of these precocious gummata syphilides, a combination of mercury and iodide of potassium is much more efficacious than is mercury alone.

DR. F. B. GREENOUGH, of Boston, read some

CLINICAL NOTES ON SCABIES.

He said that since the establishment of the special department for skin diseases at the Boston Dispensary, thirteen years ago, he had had the opportunity of studying a large number of cases of scabies, and had been much interested by the rapid increase in the number of cases seen in the past few years. The percentage of cases of scabies to cases of other cutaneous diseases had varied from $\frac{1}{10}$ per cent. in 1876 to over 13 per cent. during the past year. This great increase in frequency seemed to be one of the most interesting and important points brought out by his notes. Four-fifths of the cases seen were between 5 and 30 years of age, and only four cases were over 60 years of age.

The facts which were especially noticed were the

few cases in which typical burrows could be found; the great constancy of the manifestations on the penis in male subjects; the difference of the symptoms produced by scratching according to the situation of the lesion, and the success of treatment. He has used almost entirely an ointment consisting of two parts of sulphur, one of carbonate of potash and three of petroleum ointment, simply cautioning the patients against applying it to inflamed and pustular localities.

DR. A. R. ROBINSON, of New York, said that opening a vesicle, examining its contents under the microscope, and finding the young acari or the fæces, would settle the diagnosis in doubtful cases.

DR. E. B. BRONSON, of New York, agreed with the author of the paper as to the frequent absence of the cuniculi. In many cases he depended largely upon the elongated character of the efflorescence in making the diagnosis. In the treatment of scabies he had used a 50 per cent. preparation of naphthol with success.

DR. S. SHERWELL, of Brooklyn, had also seen an increased number of cases of scabies, a large proportion of the cases being among Scandinavians. As a prophylactic, he directed the patient to sprinkle on the sheet a teaspoonful of the dry sulphur. This acts as a disinfectant and is unpleasant to the acarus.

DR. H. W. STELWAGON, of Philadelphia, read some CLINICAL OBSERVATIONS REGARDING THE VALUE OF RESORCIN, ICTHYOL AND LANOLIN IN CUTANEOUS DISEASES.

In regard to lanolin, he said that in some cases as an ointment base this is superior to the ordinary fats in use. Where a simple protective action is desired, it is inferior to vaselin, cold cream or lard. In chronic cases, where there is infiltration and a degree of penetration is the object, lanolin is especially valuable. The writer stated that according to Liebreich, a lanolium purissimum was now manufactured, in which the cholestrin ethers were absent. The main disadvantage of lanolin as now manufactured from sheep's wool is its strong sheepy odor. In a few acute and subacute cases of eozem, lanolin for some reason proved irritating. As a rule, however, it is bland and unirritating.

TUESDAY, AUGUST 25—SECOND DAY.

MORNING SESSION.

DR. G. H. TILDEN, of Boston, read a paper entitled

TROPHONEUROSIS OF THE SKIN CAUSED BY INJURY OF THE MEDIAN NERVE.

A carpenter, 55 years of age, was wounded in the wrist by a circular saw, four months before coming under observation. The wound was parallel with the axis of the limb. Three or four days after the infliction of the injury there was loss of the tractile sense and a feeling of numbness in the last two phalanges of the fore and middle fingers. This had continued and steadily increased. Three weeks after the accident, a bulla appeared upon the terminal phalanx

of the middle finger. Similar lesions have developed from time to time upon the last two phalanges of the fore and middle fingers. The bullæ appear every two or three weeks and are unaccompanied by any subjective sensation. The skin over the affected phalanges is of a white color and of glossy texture. The growth of the nails is unaffected. There was entire loss of sensation in the skin covering the affected phalanges. The right hand is capable of exerting only one-half the power of the left. The first and second interossei muscles exhibited the reactions of degeneration.

Six weeks' treatment with the Faradic current caused decided improvement in all the symptoms. During this period only one bulla formed. He then stopped treatment and returned to work. Three weeks later all the former symptoms suddenly returned. It was proposed to the patient that an incision be made over the seat of injury with the view of determining the exact condition and if possible remedying it. The patient has not since been seen. After briefly considering the pathology of such lesions, the speaker said that the treatment of these cases consists in the use of electricity and the application of blisters over the seat of injury. A last resource is to cut down upon the affected nerve and endeavor to relieve any constriction or pressure which may be found. If no such condition is detected, resection of a portion of the nerve might be advisable, since complete section is not apt to be followed by spontaneous trophic changes and since it has been found that resection of a portion of the affected nerve is sometimes followed by the arrest of the trophic changes.

DR. JAMES C. WHITE, of Boston, read a paper entitled

NATIVE PLANTS INJURIOUS TO THE SKIN.

He enumerated over fifty species which have irritating properties, when brought in contact with the skin.

DR. F. B. GREENOUGH, of Boston, read

A FEW ADDITIONAL NOTES ON PSORIASIS.

The author, owing to the fact that a statement he had made at the last meeting in reference to the general health of the patients, had been doubted, had attempted to obtain further testimony upon this point. He found that, as a rule, patients with psoriasis were above par in general health and strength. He had records of twenty-nine cases of 1,220 cases of skin diseases, giving a ratio of cases of psoriasis of $2\frac{2}{3}$ per cent. The reader thought that the interesting deductions to be drawn from his cases were the facts that while nine cases showed symptoms of psoriasis under 10 years of age, one was first attacked at the age of 57 years; that out of twelve cases in which evidence could be obtained, four gave a decided history of the existence of disease in some member of the family, and that these cases showed such a high standard of general health. He considered this latter fact as a strong argument against the possible connection between psoriasis and syphilis.

DR. A. R. ROBINSON, of New York, described a case of

CHONDROMA OF THE UPPER LIP.

The tumor occurred in a man 36 years of age and had been growing two years. It was one inch in length by three-fourths of an inch in diameter. It was egg-shaped, the broad end having its seat in the submucous tissue among the mucous glands. The mucous and cutaneous structures were freely movable over the tumor, which was sharply limited, somewhat encapsuled, and nourished by a small artery entering at the base. Microscopical examination showed the tumor to consist of embryonic, gland, and connective tissue. There were several islands of cartilage, the largest being in the central part of the tumor. All varieties of normal cartilage were present, viz.: hyaline, fibrous and reticular, and also the variety met with in the heads of cephalopods, namely, cartilage with ramifying or branched cells. The cells showed great diversity of form and size. The body of the branched cells presented a great variety of form. Some were surrounded with a capsule, but in the majority of cases this was absent or only faintly indicated. The affection was considered to be very rare.

DR. P. A. MORROW, of New York, read a paper on

KERATOSIS FOLLICULARIS, ASSOCIATED WITH FISSURING OF THE TONGUE AND LEUKOPLAKIA BUCCALIS.

The patient, a sailor aged 21 years, came under observation in December, 1885. Five years previously, soon after beginning his seafaring life, he noticed a number of blackish points upon the back of the hands, some of which he squeezed out. Soon afterwards these appeared upon other parts of the body. They improved when he was on land, but were aggravated when he was at sea. The entire surface of the body, with the exception of the face, palms and soles was found to be seat of the follicular disorder. The ducts of the sebaceous glands were occupied by comedo-like bodies projecting sometimes one-fourth to one-half an inch above the surface. From many of the follicles small white hairs protruded. The comedos when pressed out were hard and dry. The hard portion of the comedo was continuous with an adhesive substance dipping deeply into the follicle. There was no evidence of irritative or suppurative action.

The tongue was large and rough to the touch; the surface was deeply fissured, the fissures extending to the submucous tissue. The buccal mucous membrane presented a bluish-white appearance, thickened and raised in places, forming distinct plaques which were superficially fissured. The absence of irritation or marked sensitiveness of the fissured organ was quite noticeable. Examination seemed to exclude the possibility of a syphilitic origin. The speaker referred to other cases which had been reported. He objected to the term *ichthyosis*, since that suggests a disease of a different nature. He selected the term *kera'osis follicularis* as more correctly expressing the pathological condition present, as well as indicating the anatomical seat of the disease. Drawings representing the microscopical appearances of the lesions were presented.

EVENING SESSION.

DR. J. E. GRAHAM, of Toronto, Canada, read

A CLINICAL STUDY OF SCLERODERMA.

The histories of two cases of this rare disease were related. The first patient, Mrs. R., 47 years of age, had previously suffered from rheumatism. The hardening of the skin began in March, 1882, and was first noticed over the back of the neck. It gradually spread so that in about ten weeks the integument over the greater part of the body was affected. The movements of the limbs as well as those of respiration were impeded. The internal treatment adopted was liquor ferri iodidi and liquor arsenitis. A Faradaic bath over the surface of the skin was used. In six weeks the skin began to grow softer, and in ten months the patient was quite well. There has been no return of the difficulty.

The second patient, Mr. H., aged 37, came under observation in May, 1886. There was a history of hereditary rheumatism. The disease had commenced some months previously. The first symptoms were stiffness of the limbs with oedema of the lower extremities. Then hardening of the skin over the hips was noticed, this gradually spread and was accompanied with pigmentation. The treatment consisted in the administration of potassium iodide at first, and latterly of salicylate of sodium. There has been some improvement under this treatment.

In his remarks in connection with the disease, the speaker referred to the following points: 1, that the disease is found principally in temperate climates and occurs in seasons when there are sudden changes in the weather; 2, that it is more closely related to rheumatism than has been supposed; 3, that although morphea has in all probability a similar pathological origin to scleroderma, yet the clinical distinctions are so marked, that at present it is expedient to treat it under a different name.

DR. LE GRAND M. DENSLOW, of St. Paul, Minn., read a paper on

CARCINOMA CUTIS.

The patient, aged 49 years, had been an invalid for several years. He had had a severe pleurisy of the right side and presented the physical signs of absence of the right lung. The skin of the whole right chest was covered with a nodular new growth, which presented no ulceration. The older portions of the growth were covered with thickened epidermis and thick brown scales. There was slight enlargement of the axillary glands. The different nodules were not movable beneath the skin, but the whole mass was free from the fascia. The duration of the growth was seven months. The patient died four months after coming under observation.

The autopsy showed obliteration of the right lung. The left lung presented many small solid nodules. In the mesentery there was a nodule one and one-half inches long by one-half inch in diameter. The microscopic examination of these masses showed that in them all connective tissue preponderated. The growth on the skin occupied the papilla and the deeper portions of the corium. A plaster cast and a drawing of the case were presented.

DR. R. W. TAYLOR described two cases which were for a time looked upon as cases of cancer of the nipple, both in men. They eventually turned out to be cases of hard chancre.

DR. I. E. ATKINSON, of Baltimore, read a paper on
SCARLET FEVER AND SCARLATINIFORM ERUPTIONS
FOLLOWING INJURIES AND OPERATIONS.

The following conclusions were presented:

1. Unprotected persons who have suffered injury or undergone operations are much more liable to scarlet fever than healthy individuals. This probably holds good with reference to other infectious diseases.

2. When an epidemic tendency to these symptoms prevails after injuries and operations, it may be concluded that true scarlet fever is present.

3. Septicæmia is occasionally accompanied with a scarlatiniform eruption.

4. Medicinal eruptions, especially from cinchona alkaloids, may follow accidents and injuries.

DR. P. A. MORROW, of New York, said that carbolic acid and iodoform dressings will often produce rashes presenting the objective appearances of scarlet fever. There is another eruption known as the "doctor's rash" which appears upon the persons of sensitive individuals stripped for examination.

DR. L. N. DENSLOW described the case of a young woman who stated that a scarlatiniform eruption always appeared upon her body on exposure to sunlight. In order to test the matter, she was directed to come to the hospital closely veiled and gloved. She was placed in a dark room and one glove removed. A ray of sunlight was then allowed to fall upon the hand, and at once a strip of erythema appeared. The same occurred on the face when it was exposed.

FRIDAY, AUGUST 27.—THIRD DAY.

MORNING SESSION.

DR. S. SHERWELL, of Brooklyn, read a paper entitled

REMARKS AND QUERIES ON AND AS TO THE RELATIVE
FREQUENCY OF MOLES AND THEIR PATHOLOGICAL
CHANGES ON THE HEAD AND FACE.

These affections receive very slight notice in works on dermatology. In looking up the statistics of one of the institutions with which he is connected, he found that in a period of eighteen months he had seen forty-seven cases suffering with neoplastic and hypertrophic growths. In thirty-six of the cases the growths occupied the face and head. In only eleven cases were the growths found on the body and limbs. Seventeen of the cases in which the growths were on the face were classed as epithelioma. It might be urged that the exposure of the unclothed portions of the body would lead to the formation of neoplasms and the occurrence of destructive activity in them. If that were so, why should not telangiectatic deformities, naevi, etc., undergo degeneration? The speaker had never seen malignant action, or what simulated it, in such growths. Mechanical irritation of the parts might be considered one reason for the frequency of these growths and their malignant

tissue alterations; but other parts of the body would seem more exposed to irritation than is the face. Moles, and similar growths, in other situations than the face, seem less likely to undergo destructive pathological changes.

The most rational explanation for the frequency of these growths in the situations described, is the activity of the circulatory nutrition in these locations, which most favor hyperplasia. If, however, we accept the above hypothesis, why should these errors of the capillary system, such as naevi, not oftener degenerate? He had often operated on the latter deformities, often causing much irritation, but had never seen more than a slight keloid change result. The speaker then referred to the special danger of malignant degeneration which attended the presence of moles in persons of advanced life.

In regard to treatment, he had come to the conclusion that when malignant action is either present or suspected, the combination of Volkman's curette, followed by the actual cautery, is the most efficient and easiest method of treatment. Of all escharotics, he preferred the liquor hydrargeri nitratis.

DR. I. E. ATKINSON said that the probable explanation of the frequency of the presence of moles, etc., upon the face as compared with other portions of the body, is that when in this situation, patients seek relief, while when covered with the clothing attention is not attracted to them.

DR. JAMES C. WHITE remarked that while these formations are not more frequent on the face than on other portions of the body, yet that they undergo degeneration and form epitheliomatous new formation on the face more frequently than elsewhere can be doubted. He had never seen angiomatous formations undergo the so-called malignant change, but they do undergo degenerative processes tending to a spontaneous cure.

DR. L. N. DENSLOW had employed as a caustic a solution of one drachm of bichloride of mercury in one ounce of traumatacin. Its application is not painful at first, and does not excite inflammation for some time.

DR. W. A. HARDAWAY, of St. Louis, read some
NOTES OF A CASE OF EXFOLIATIVE DEMATITIS (PITYRIASIS RUBRA?) WITH BULLOUS LESIONS.

February 21, 1886, the author was called to see Mrs. A., with an annoying disease of the skin. The patient was 45 years of age, stout and somewhat nervous. The present disease came on Feb. 1, after a night of fatigue and exposure. The following day a red patch appeared on the pit of the stomach. Others developed soon, running together, leaving no healthy skin between. There was very little scaling at first, and no moisture. When seen by the author the skin presented the usual appearance of pityriasis rubra. There was neither moisture crusts nor appreciable infiltration. The skin was shining and of a violaceous hue. In the morning a handful of scales could be gathered from the sheet. The face was not involved. Three or four days after the first visit there appeared upon the thighs, abdomen and buttocks a number of tense bullæ. Their appearance

was preceded by a distinct chill and followed by a moderate elevation of temperature. The blisters did not run into each other. The bullæ appeared in successive crops of not more than a dozen, each crop being preceded by a chill. Quinine was freely administered, and at the end of a week the bullæ ceased to appear and the patient gradually improved.

The writer thought that this and other cases which he had seen showed diseases usually supposed to run a dry course may, under certain circumstances, be complicated with lesions containing fluid.

DR. G. H. TILDEN, of Boston, reported

A CASE OF PROBABLE TUBERCULOSIS OF THE SKIN.

A healthy-looking boy of 2 years of age was first seen in July, 1885, presenting six or eight cutaneous lesions scattered over various parts of the body. They were slightly elevated above the level of the skin, of a bright red color, which disappeared entirely on pressure. These nodules were hard to the touch, with borders of sensible infiltration. These lesions had appeared within the previous five months and had been very slow in growth. During the previous three months there had been failure in appetite and strength. Softening took place in the nodules with formation of pus, which discharged and was followed by cicatrization. About two weeks after the first visit a fluctuating swelling made its appearance. The general health became visibly affected. In November there appeared in the left buttock a swelling which gave an obscure sense of fluctuation. In the proximal phalanx of one finger there appeared a pyriform enlargement resembling that seen in dactylitis syphilitica. The child was again seen in February. The swelling in the buttock had increased in size and there was more fluctuation in it. There was at this time sufficient outward curvature of the lumbar vertebræ to justify a diagnosis of Pott's disease. From the course of the disease the speaker thought the most probable diagnosis to be tuberculosis of an unusual form.

DR. DENSLOW made a supplementary report with reference to

THE TREATMENT OF ACNE BY THE USE OF SOUNDS.

At the last meeting he had reported five cases in which this plan of treatment had been of value. Four of these cases were adults and all had remained well. The fifth case was that of a boy about 14 years of age, and in this case relapse had occurred.

A communication with reference to the organization of a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was received and the following committee of conference, to report at the next annual meeting of the Association, was appointed: Drs. H. G. Piffard, of New York; F. B. Greenough, of Boston; R. B. Morison, of Baltimore; C. H. Tilden, of Boston, and Le Grand N. Denslow, of St. Paul.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President—Dr. H. G. Piffard, of New York.

Vice-Presidents—Dr. F. B. Greenough, of Boston; Dr. R. B. Morison, of Baltimore.

Secretary—Dr. C. H. Tilden, of Boston.

Treasurer—Dr. Le Grand N. Denslow, of St. Paul.

The Association then adjourned to meet at the call of the Council.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, May 20, 1886.

THE PRESIDENT, H. O. MARCY, M.D., IN THE CHAIR.

H. J. HARRIMAN, M.D., SECRETARY.

DR. W. O. HUNT read a paper entitled

PUERPERAL INSANITY.

The paper was based upon two cases of puerperal insanity occurring in the practice of the writer.

Mrs. H., married, colored, 23 years of age, primipara. Labor was long and tedious, though uncomplicated. Nothing abnormal occurred until the sixth day, when patient became talkative, sleepless and delirious. She developed a mild case of insanity which, under absolute quiet and plenty of nourishment, resulted in recovery in six weeks.

Case 2.—Mrs. M., supposed to be in last part of seventh month of pregnancy; married against her wishes; of nervous temperament, but no heredity. Had a fall, striking upon left side of abdomen, which caused pain and soreness. On the day following the fall labor pains set in and a small and feeble child was born without complication. On the day following delivery there was much pain at site of injury; pulse 90; temp. 99.5, with a slight chill. For about a week patient improved, the pain disappearing and temperature and pulse becoming normal. At that time patient was prostrated by shock due to the fact that her husband came home drunk and tried to sleep with her. Patient became delirious and talked all the time; pulse 120, temp. 100. For about two weeks patient continued to grow worse, both mentally and physically. At the end of that time a chill occurred and slight dulness was discovered over lower lobe of right lung. The lung symptoms subsided in two days, but left patient much prostrated. Urine and feces were passed involuntarily in bed; mouth and teeth were thick with sordes; perspiration profuse and foul smelling; intelligence entirely wanting. From this low condition she soon began to rally, and in about three months from beginning of attack had entirely recovered.

Puerperal insanity is confined to a limited period following childbirth, and is intimately connected with that process. It is not of rare occurrence—one-twelfth of the women admitted to Salpetriere presenting symptoms of this trouble—but among the higher classes it is not so frequent. Primipara are more subject than multipara, and women between 30 and 40 years of age, who are confined for the first time, are especially liable. Heredity is frequent. In most cases conditions producing debility, exhaustion or mental depression, such as post-partum hæmorrhage, complicated labor, or anæmia, precede, the

attack. The theory formerly held that puerperal insanity was due to some uterine lesion, has been discarded. The theory of the septic origin of this disease was introduced by Sir James Y. Simpson, and, with various modifications, has been adopted by many later writers. The fact that albumen is often found in the urine has given rise to the theory that the poisoning is uræmic.

The attack is often preceded by restlessness and loss of sleep. At an early period there is an agitated manner, a restless eye, an anxious expression of the face, an irritable temper, loss of memory, etc. The language becomes incoherent and is often obscene. Delusions appear and suicidal or homicidal tendencies may develop. In bad cases the milk and lochia are entirely suppressed, and the tongue and teeth become foul with sordes. The urine is scanty and high colored, and the bowels are generally constipated, though diarrhoea may exist.

The majority of cases result in recovery within a period of three months. After that time the chances of complete recovery are much lessened. Extreme rapidity and weakness of pulse points to a fatal issue.

Where family or personal history shows a liability to this trouble, efforts should at once be made to anticipate any untoward symptoms by means of good nursing, absolute quiet, judicious diet, etc. When the disease has appeared treatment must be mainly directed to keeping up patient's strength. The two things most needful are sufficient food and sleep. If patient refuses food enemata should be tried, and, if unsuccessful, forced feeding. A free purge should be given at the outset, and the bowels kept open during the attack. Sleep should be secured if necessary by means of chloral, hydrate or bromide of potash, or a combination of the two. Judicious nursing, with a cool and well ventilated room, are indispensable. When convalescence is established a change of air and scene, together with other means to build up the general health, are of value.

DR. Z. B. ADAMS did not think that puerperal mania differed materially from ordinary acute mania. He had had some experience as assistant at the Taunton Asylum, and had always found that the refusal to take nourishment was a troublesome feature of many cases. The late Dr. Ray has suggested that if the patient be partially etherized she will eat without trouble. A singular fact in these cases is the tendency of patients whose character is irreproachable to use coarse and obscene language.

DR. HENRY M. FIELD read a paper on

THE TREATMENT OF CONSTIPATION.

(See page 290.)

DR. Z. B. ADAMS said that he could add but little to Dr. Field's excellent paper. Next to cultivating the habit of regular evacuations he regarded kneading the bowels as the most pleasant and efficient means of relieving the constipation. Dr. Adams asked the opinion of the members in regard to the value of cascara sagrada.

DR. FIELD considered cascara sagrada of value, and the solid extract as the most pleasant and effi-

cient form of the remedy. It is a stimulant and acts like senna, though it produces less peristalsis. In many cases of constipation in feeble infants he regards it as the only safe and proper remedy.

DR. L. F. WARNER considered the paper a valuable one, but found in it no reference to what he considered "nature's physic," *i. e.*, healthy bile. He thought that the secretion of the liver should be attended to in all cases, and that mercury in some form was indicated in the treatment of all cases of constipation. He attributed the action of some purgatives, like elaterium, which produce copious watery discharges, not to any specific action upon the glandular system of the intestinal tract, but simply to increased endosmosis and exosmosis.

DR. WM. G. WHEELER said that most of the agents for the relief of constipation were not new, but that the practical application of the remedies had been improved. Some of the agents formerly much used but now practically discarded, such as cream of tartar, etc., are of great value. Idiosyncrasy is an element in the treatment of every case which should not be overlooked. Dr. Wheeler described a case of a lady who from childhood had had but one evacuation of the bowels each month. In this case enormous dilatation of the colon existed, but the condition was somewhat improved by the use of aloin, nuxvomica, and careful attention to diet and habit.

DR. W. THORNTON PARKER spoke of the custom of some tribes of American Indians of using frequent and powerful purgatives. The alarming prevalence of consumption among them is probably due to the debility resulting from such hypercatharsis. Tobacco seems to act as a laxative in many cases. Dr. Parker stated that tartrate of soda in effervescent form is a laxative the excellence of which is not fully appreciated. The triturates of calomel and ipecac, made by Frazer & Co., are of great value, especially for children. The common American privy is the cause of many cases of constipation. They are at a distance from the house, are cold and inconvenient, and many women prefer to undergo the dangers and discomforts of constipation rather than endure the exposure incident to a visit to the privy.

DR. W. O. HUNT said that the constipated habit was due primarily to a disregard of the calls of nature, so that the lower bowel in time became distended and failed to respond to the irritation of the faecal mass. He had found the gluten suppositories, sold by the Health Food Co., of Boston, an efficient and agreeable agent in procuring an evacuation, and also in permanently relieving the constipation.

DR. E. W. CUSHING had used electricity in the form of the faradic current with advantage in the treatment of constipation. This agent is of special value in cases where the trouble is due to atony of the muscular elements of the bowels. The tight waist worn by girls and the belt used by boys are pernicious in their effects. They interfere with the function of the bowels by preventing the passage of the faeces along the ascending colon. This interference may produce dilatation of the colon and thus cause a liability to typhlitis or perityphlitis. Suspenders are better and safer.

DR. PARKER did not think that the belt worn by men and boys could produce the ill effects described by Dr. Cushing. He had had experience in treating sailors and did not find them peculiarly liable to constipation, although they invariably wore a belt, or at least trowsers which were tight at the waist.

DR. CUSHING, in reply, said that the belt or tight waist of the sailors does not constrict the abdomen, but that their trowsers are suspended from the hips. This would explain their freedom from the bad effects of the ordinary belt.

DR. I. W. STARBIRD wished to bear hearty testimony to the value of cascara sagrada. He had used it with success in ninety-four cases, and considered it especially valuable in the treatment of children. In doses of fifteen drops of the fluid extract he had relieved cases in which natural evacuations had not occurred for six years.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Lack of Hospital Accommodation on the Guion Steamer "Arizona"—Medical Interference Resented by the Manager—A Doctor's Life at Sea—Department of Bacteriology, British Medical Association—Vaccination in Leicester.

A matter of great interest to the general public has recently been broached by a Dr. W. V. Barrè. It appears from a lengthy communication addressed by that gentleman to a medical paper, that he was employed as surgeon on board the Guion Atlantic liner, "Arizona," for three months. His last voyage in that vessel was commenced on May 15. Before sailing, he deemed it part of his duty to call the attention of the manager of the Guion line, to the want of proper hospital accommodation on board the "Arizona." It would appear that there are four hospitals on board that vessel. Two are situated on the main deck, in the "permanent steerage," and are only separated by a thin partition or bulkhead from the steerage itself. Being thus placed, it is clear these receptacles are useless for the accommodation of patients in event of infectious disease appearing on the ship. The remaining two "hospitals" are situated on the upper deck in the ships bows, under the "turtle back," which serves as a protection against heavy seas. These enclosures, Mr. Barrè admits, can be made to look presentable enough when the ship is in port. At sea, however, they are not only always soaking in bad weather but are only to be reached on such occasions at considerable personal risk, from the waves which sweep the open and intervening deck space. For seven or eight months of the year, these latter berths could not be used at all for hospital purposes, on account of the stormy weather. The climax of the details regarding these deck hospitals of the "Arizona," is reached, however, when Mr. Barrè tells they were commonly used as dog kennels, etc., that on one occasion a passenger's dog,

stabled in one of them, was actually drowned during a voyage. What the fate of any unfortunate passenger would have been who might have chanced to be lying sick and helpless in such a berth, may perchance, require no great thought to discern. The large vessel just named, carries as many as 1,118 persons on a voyage. Yet, as far as her hospitals go, she is utterly unprovided with what is absolutely necessary accommodation in view of the possible contingencies and accidents of sea life.

The story told by Mr. Barrè goes on to relate how when he directed the attention of the Guion officials to the absence of needful ventilation in one of the steerages—which must prove a Black Hole of Calcutta in a small way if Mr. Barrè's details are correct—he was informed that he had no right to direct attention to any such defects. If the Board of Trade officials passed the ship for sea, argued the manager, that was all that was required. This opinion was given despite the fact that passengers who had occupied the ill-ventilated steerage had actually lodged a numerous signed protest against the fashion in which they were treated. Mr. Barrè found practical experience of the aphorism that the ways of reformers, like the ways of the wicked, are hard. He was dismissed from the Guion service ostensibly because he desired to make his ship comfortable and healthy. This is without doubt a by no means novel experience of ship surgeons, and the sooner Governments bestir themselves in the matter of supervising the medical department of the mercantile marine the better it will be for wayfarers by sea and surgeons anxious to do the duty which they are appointed to perform.

A second correspondent gives an equally important glimpse of the doctor's life at sea. Having reason to complain of the unsanitary condition of a ship, he consulted the captain before sending in a report to the owners. "You'll get yourself disliked," said the seaman. On this occasion, however, the report was sent and was acted upon, "but," adds the surgeon, "it might have been my dismissal from the service." Again, it appears that the ship surgeon is often by no means treated courteously in respect of ship regulations. A correspondent assures the public that in a well-known Atlantic company the surgeon is not allowed on the quarter deck after the first day or two, when the ladies are supposed to have overcome their seasickness. If, again, this statement is correct, it is obvious that there exists some singular anomaly in excluding from passengers' society an officer whose education and training have in nearly every case exceeded that of the captain himself. Up to the present the assertions of Mr. Barrè have been in no way disproved as to the method of suppressing sweetness and light on the medical side of the Guion establishment, or what the second correspondent has to say regarding the curious courtesies observed in the medical service of other lines. The matter calls for investigation, and until the accounts before the public are disproved, it appears that the position of a doctor at sea is susceptible in certain quarters at least of very considerable improvement.

One of the chief centres of interest at the recent meeting of the British Medical Association at Brighton

was a department of bacteriology specially arranged at the request of the President by Dr. Edgar Crookshank. The collection included apparatus and specimens illustrative of the processes of cultivating microbes, as well as a remarkable series of photographs, the result of a special investigation by Dr. Crookshank into microscopic photography as a means of pathological research, in some of which the growths were represented as if magnified 9,000 times. The cultivations, all prepared in England, were in gelatine, agar-agar, hay infusion, blood serum, bread paste and potatoes, the latter showing some fine growths of micrococcus prodigiosus, the ruddy color of which, when seen on food, has been at times regarded as a miraculous manifestation of blood stains. The collection also included the comma bacillus of Koch, being the bacillus associated with Asiatic cholera, as well as pneumococcus, the microbe associated with inflammation of the lungs, which, until the discovery of this microbe, was not suspected of being associated with parasitic infection. Another specimen was the foul blood in bees, the development of which had been fully worked out, whilst there were numerous specimens of the bacillus anthracis, well known in connection with M. Pasteur's experiments in the inoculation of sheep and cattle as a protection against splenic fever.

According to statistics just issued for the last six months, out of 2,500 children born in Leicester, only 300 were vaccinated. The authorities have therefore declined to apply further coercion, it being evident that the great bulk of the population are determined to resist the enforcement of vaccination. Dr. Julius Dreschfeld this year delivered the Bradshaw Lecture "On Diabetic Coma."

G. O. M.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Development of Purulent Infection as a Sequel of Simple Non-Traumatic Pneumonia—An Optical Illusion—A Correction—Solution for Chapped or Sore Nipples.

Professor Jaccoud lately read a paper at the Academy of Sciences, the purport of which was to demonstrate the development of purulent infection, as a sequel of simple non-traumatic pneumonia. According to the author, the evolution in such a case is as follows: An individual in perfect health, attacked with acute pneumonia, the malady presents the characters and the course of marked simple pneumonia, nothing present to foresee the terrible incidents of which it may be the starting point. In ordinary cases, the acute phasis reaches its term, the fever ends, but the febrile defervescence is not followed by complete local repair, the remains more or less extensive of the pneumonic focus persist without any alteration. After an indefinite period during which the malady is stationary, the situation of the patient is aggravated, and he succumbs after having presented indubitable signs of a state of infection, or he dies suddenly without any previous aggravation of his condition. At the autopsy, one notices spots of sup-

uration in the pneumonic remains, and diffuse purulent foci, either in the limbs, or in the viscera. The patient having been seized with pneumonia in perfect health, the pneumonic remains having been during several days the only lesion present, it is certain, taking the accidents chronologically, that the supuration of the lung is the starting point of the purulent foci, and of the general infection of the organism. Moreover, if these foci be submitted to microbial investigations, one can seize and place in evidence the intermediate agents between the primary and secondary lesions, for the same micro-organisms which are discovered in the suppurated spots of the lung, are found in the blood and in all the foci without exception. This pathological evolution, Professor Jaccoud observed them in two cases, the full history of which he submitted to the Academy, and the author thinks that both the cases sufficiently demonstrate the development of purulent infection following non-traumatic pneumonia, primarily and clearly normal at its onset. The pathogenic connection is revealed with complete evidence, the pneumonia, arrested in its resolution, merges into the formation of pus in the lung. From this initial focus, the pyogenic agents penetrate into the blood and determine, on a more or less greater number of points, spots of supuration of the same nature. This is a confirmed type of pyohemia by microbial migration. There are in medical literature, examples of articular suppurations occurring in the course of, or following pneumonia, but these cases, which differ notably from those reported by M. Jaccoud, have been differently interpreted by the authors, and, consequently, their observations cannot in any way militate against the priority which the learned Professor claims for his demonstration.

It is known that when the eye looks for some time, in complete obscurity, at an immobile object of small diameter and feebly lighted, it very frequently happens that this object appears distinctly to move with a certain rapidity in a determined direction of the field of vision. This phenomenon, when it occurs, according to Dr. A. Charpentier, the author of the above remarks, is very striking, and nearly all the persons on whom he tried the experiment have realized the fact. This optical illusion is an appearance analogous to the transit of a shooting star, but less rapid. In a paper giving an account of his researches on this curious phenomenon, and which he communicated to the Academy of Sciences, Dr. Charpentier deduced the following conclusions: 1. The illusion really takes place in the fixed eye looking at a fixed object. 2. The diverse attitudes of the eye have no influence whatever on the phenomenon. 3. It is possible to provoke voluntarily the apparent displacement of the object in a determined direction. 4. The visual illusion, when it is not provoked by the observer, might perhaps be explained by inconscient efforts produced in the brain in a manner almost continuous and simultaneously with the phenomenon well known of the association of ideas. M. Charpentier, however, gives this explanation as a simple hypothesis, and leaves it to other investigators to solve the problem.

In my letter published in *THE JOURNAL* of July 10, in giving an account of a horny tumor of the scalp in a woman 51 years of age, I was erroneously informed that she had died. At the meeting of the Medical Society of Hospitals, on the 25th of June last, Dr. Vidal exhibited the horn, which was removed by Dr. Dubrandy. This horny tumor is said to be the largest on record that has been seen in a human subject. It was removed by elastic ligature. Since its removal it has been reproduced, and had then attained (June 25) a length of two centimetres. Dr. Dubrandy proposed to excise the portion of the scalp in which this production is implanted.

Dr. Pinard, a well known obstetrician, recommends the following solution in the treatment of chapped or sore nipples: Boric acid 6 grammes, distilled water 200 grammes. As soon as the cracks make their appearance, or even as soon as the patient feels the least sensitiveness in suckling her baby, the solution should be applied to the nipples and alveola by means of a piece of linen folded four times thick, over which is to be placed gummed or varnished silk, and the whole covered with a layer of cotton wool supported by a bandage. Dr. Pinard states that even a saturated solution of four per cent. may be employed without inconvenience. A. B.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

LUMBRICIDS IN THE LARYNX.—A few weeks ago a girl was suffocated by a number of lumbricoid worms becoming impacted in the larynx, she having presumably vomited them.

PROFESSOR FERD. RITTER VON ARLT, the distinguished ophthalmologist of Vienna, is said to be suffering from gangrenous thrombosis of the leg.

VIENNA MEDICAL FACULTY.—It is said that after the beginning of next year the vacation courses will be discontinued.

ADAMS COUNTY, OHIO, MEDICAL SOCIETY.—Quite a number of the physicians of Adams County, Ohio,

met in West Union, on June 17, and organized the "Adams County Medical Society" by the election of the following officers: President, Dr. David Coleman; Vice-President, Dr. C. W. Salisbury; Secretary, Dr. J. W. Bunn; Treasurer, Dr. C. S. Corboy. The next meeting will be Oct. 21, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 28, 1886, TO SEPTEMBER 3, 1886.

Capt. L. W. Crampton, Asst. Surgeon, relieved from further duty at Bellevue Rifle Range and granted leave of absence for one month, to take effect before rejoining his proper station (Ft. Bridger, Wyo.). (S. O. 108, Dept. of the Platte, Aug. 28, 1886.)

First Lieut. L. Wood, Asst. Surgeon (recently appointed), ordered to report by letter to the commanding general Dept. of Arizona for assignment to duty. (S. O. 202, A. G. O., Aug. 31, 1886.)

First Lieut. Freeman V. Walker, Asst. Surgeon (recently appointed), to report in person to the commanding general Dept. of the East for assignment to duty. (S. O. 203, c. s., A. G. O.)

First Lieut. Chas. F. Mason, Asst. Surgeon, relieved from duty in Dept. of the East and assigned to duty in Dept. of Arizona. (S. O. 203, A. G. O., Sept. 1, 1886.)

First Lieut. Chas. F. Mason, Asst. Surgeon, relieved from duty in Dept. of the East and assigned to duty in Dept. of Arizona. (S. O. 203, A. G. O., Sept. 1, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING SEPTEMBER 8, 1886.

Dickson, S. H., P. A. Surgeon, detached from the Naval Academy, Oct. 1, 1886, and ordered to Navy Yard, Washington.

Lippincott, J. G., P. A. Surgeon, ordered to Naval Academy, Oct. 1.

Shippen, E., Medical Director, detached from Naval Hospital, Philadelphia, and ordered to attend officers of the Navy and Marine Corps at Philadelphia not otherwise provided with medical aid.

Hord, Wm. T., Medical Director, detached from Examining and Retiring Boards at Washington, Oct. 5, and ordered to Naval Hospital, Philadelphia, Pa.

Dean, R. C., Medical Director, ordered to duty as member of Examining and Retiring Boards at Washington, Oct. 5, 1886.

Bransford, J. F., Surgeon, detached from U. S. S. "Iroquois," and ordered to Naval Hospital, New York.

Hall, C. H. H., P. A. Surgeon, detached from Naval Hospital, New York, and ordered to Naval Hospital, Yokohama, per steamer of 21st inst.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED SEPTEMBER 4, 1886.

Bailhache, P. H., Surgeon, to proceed to Cape Charles Quarantine as Inspector. Aug. 27, 1886.

Fessenden, C. S. D., Surgeon, granted leave of absence for thirty days. Aug. 30, 1886.

Godfrey, John, Surgeon, to proceed to Biloxi, Miss., and investigate alleged yellow fever cases. Sept. 1, 1886.

Irwin, Fairfax, P. A. Surgeon, granted leave of absence for thirty days. Sept. 2, 1886.

VENOUS BLOOD TUMORS OF THE CRANIUM

in Communication with the Intra-Cranial Venous Circulation, Especially the Sinuses of the Dura Mater.¹

BY WM. M. MASTIN, M.D.,
OF MOBILE, ALA.

The following propositions are submitted as the result of my study of this class of cranial venous tumors:

1. Cranial venous blood tumors communicating with the dural circulation are to be classified into three divisions, namely: the congenital, spontaneous, and traumatic.

2. These classes are divided, upon both anatomical and pathological grounds, into two species or varieties: *a*, the diffused, produced by a perforation of the cranial plates and the wall of the subjacent sinus, resulting in a limited extravasation of blood beneath the scalp and thus forming a blood-cyst in direct or immediate communication with the affected sinus; and *b*, the venous or vascular, in which the tumor is directly formed at the expense of the venous coats, and includes in its scope the sinuses, the venæ emissoria, and the diploic vessels.

3. The venous type is the commonest in point of occurrence, and of this type, varicose involvement of the emissory vein is the most frequent form; whilst the diffused is the rarest of all the varieties.

4. The diffused variety is especially characteristic of the spontaneous and traumatic groups. The venous or vascular type occurs most frequently in the congenital class, but at the same time is often met with in the spontaneous division.

5. The medium of communication with the intra-cranial circulation is, in the very large majority of instances, represented by the superior longitudinal sinus, particularly its central and posterior portions. The emissoria Santorini most often implicated are, probably, the superior or posterior parietal emissories, which pair, also, are the most constant and uniform in their existence. When the diploë is involved the frontal region is the usual seat—no instance of a similar occipital formation having been observed.

6. In a causal relation, some morbid action in the venous walls is notably prominent in the congenital

class; in the spontaneous group, atrophic or rarefying osteitis ranks first as a cause, and venous disease secondly; and in the traumatic division, direct injury, which nearly always means fracture, is the only etiological factor.

7. Palliative measures for retarding or arresting the progress of the growth, and certain forms of compression intended to act as a curative agent, are useless applications—the latter, in addition, being capable of producing alarming head symptoms, and hence may be harmful.

8. General surgical interference is not called for, because the history, nature, and progress of the lesion is opposed to indiscriminate operation, being of that character to render such treatment unnecessary. When, however, operation is deemed expedient or is demanded, the following methods seem to be open for adoption:

First, if the growth be either of the diffused type, or that form consisting of a varix-sinus, exposure and ligation of the pedicle (if such exist), or, if necessary, deligation of the sinus in its course, the trephine being boldly employed to furnish requisite space for the necessary attending manipulation. The lateral ligature and suture, when applicable, are preferred to complete ligation.

Second, if the tumor be composed of varicose emissory vessels, or, perhaps, of diploic dilatations, either electro-puncture or strangulation of the base are justifiable procedures, but preference is given to electro-puncture.

Since the discussion of the subject of cranial venous blood tumors communicating with the cerebral circulation, particularly through the medium of the dural sinuses, in an article which appeared in the April and May issues of the *Annals of Surgery* for 1885, I have succeeded in collecting so much additional data relative to this important pathological formation, that I have decided to embody the results of my entire research in a second and more complete monograph.

This has seemed proper and desirable not only from the natural surgical interest which must attend all investigations and compilations leading to the clearer elucidation of an affection which, in both actual occurrence and literary records, constitutes a class of comparatively rare lesions, but also on account of the necessity of a very material change in some of the conclusions and deductions arrived at in my preceding brochure, which this increased information now renders obligatory. It is to this enlarged

¹ Read in the Section on Surgery, at the Thirty-Seventh Annual Meeting of the American Medical Association.

and more comprehensive examination of the subject that I desire to invite your attention.

With the simple explanation just made I shall not attempt to apologize for the numerous repetitions and dry details, especially in the references to clinical histories, which compose a certain part of these remarks, and will remain content in the belief that the topic possesses attraction equally great for others as for myself. The infrequency of all reference to this interesting and uncommon form of sanguineous tumor in recent or modern surgical treatises, is a matter of considerable surprise and comment. Notwithstanding the occasional mention of the lesion, with the moderate number of clinical records which are to be found scattered here and there throughout the broad field of surgical literature, to say nothing of the manifest inherent importance of the formation, together with its relation to general surgery, I am unacquainted with more than a half-dozen works, among the vast profusion of surgical writings which have appeared subsequent to twenty years ago, that make the slightest allusion to the subject,—and especially does this observation obtain of American and English publications.

As representing the most prominent among those authors referring to the malady within this period, may be named MM. Fallin and Duplay, who, in their admirable treatise on Pathology (*Traité Élémentaire de Pathologie Externe*, Paris, 1868-9), devote a short but concise and instructive section to a consideration of the subject; Legouest and Servier in their valuable article on the *Cranium* contained in the *Dictionnaire Encyclopédique des Sciences Médicales* (1e Série, Paris, 1879), contribute an important and comprehensive chapter on these sanguineous tumors; Bergmann (*Deutsche Chirurgie*, 1880); and Dr. Gross (*System of Surgery*, Phila., 1882), who notices the lesion in a brief paragraph, and without the addition of any special or original observations.

Prior to the date specified, however, surgical annals are not quite so barren of such allusions, as is amply indicated by the array of facts and clinical cases presently to be detailed, together with the bibliographical collection appended to this essay, and the most important of which are the contributions of Burns, Demme, Dupont, Stromeyer, Duplay, Verneuil, Jules Dubois, Middlesdorff, Burchard, Dufour, Hecker, Michaud, Chassaignac, Melchiori, Azam, and Hutin, to which publications we are largely indebted for much of the knowledge that we possess concerning these types of cranial blood-tumors.

It is of interest to note, also, the various appellations given to the affection,—among other less distinctive terms, it being described under the several designations of: *Varix verus cirsoideus* and *varix verus circumscriptus*; *fistule osteo-vasculaire*; *erectile tumors of the skull communicating with the superior longitudinal sinus*; *sinus pericranii*; *varix sinus verus extra-cranium congenitalis*; "*venous tumors of the cranial bones*"; *varix spurius circumscriptus venæ diploicæ frontalis*; *sanguineous tumors of the vault of the cranium in communication with the intra-cranial venous circulation*; *sanguineous herniæ of the vault of the skull by communication, through openings*

in the bone, of the meningeal vessels with the exterior integument; *varicose veins or venous varicosities of the skull*; *a new form of tumor of the vault of the cranium, produced by the blood in communication with the intra-cranial venous circulation*; *extra-cranial venous tumors connecting with the intra-cranial venous circulation*; *subpericranial venous tumors*; and *reducible sanguineous tumors of the vault of the cranium*. These titles were based upon some salient or distinguishing feature, and at the same time they furnish a fair insight into the individual opinions entertained of the pathology and origin of these formations by the authors respectively adopting them.

Recognizing the scattered and, under existing circumstances, often inaccessible condition of the literature, it has seemed particularly desirable that some attempt be made to gather these fragments together. Therefore, having succeeded in collecting a sufficient, if not the larger, portion of these fugitive contributions, from which, it is believed, some intelligent and decided inferences can be drawn; or, at least, enough to allow generalization, I shall endeavor in this second article to lay the collated material before the profession in a more compact and tangible form.

Classification.—Considering all the pathologico-anatomical facts, combined with the various hypotheses relative to the subject, to which I shall advert hereafter, these tumors should be divided, on account of the period and method of their formation, into the following classes:

- I. Congenital.
- II. Spontaneous.
- III. Traumatic, or cases resulting from *direct* traumatism.

It appears warrantable, also, both from the etiology and special structures involved in each, to make two divisions of these three classes or groups, namely:

1. The Simple or Diffused.
 2. The Venous or Vascular.
1. The *simple* or *diffused* comprises those cases in which the blood effusion takes place immediately beneath one or all of the scalp layers—dissecting up these tissues and thus forming the tumor-walls—and which may be caused by spontaneous or other perforation of the cranial parietes with opening into the sinus, as in rarefying osteitis, and from many traumatisms.
 2. The second division, the *venous* or *vascular*, covers those cases formed through direct implication of or morbid action in the venous coats, the walls of a sinus, an emissory vessel, diploë vein, as in ectasia of the sinus wall through a normal or abnormal skull perforation, in circumscribed and multiple varicosities and dilatations of the venæ emissoria, in ruptures of these emissory veins, and in dilatations of the diploëic vessels with loss of osseous substance.

These two divisions again admit of still another division, dependent upon the particular features of the tumor, that is:

1. The cyst or pouch variety, which may be further subdivided into:
 - (a) Fusiform,
 - (b) Sacciform,
 - (c) False, and

2. The varicose or erectile variety.¹

1. The *cyst* or *pouch* variety is that form of the lesion which is characterized by the formation of a simple (seldom more than one) cyst or cavity; and therefore includes circumscribed dilatation of a vena emissorium (fusiform); an ectasia or hernia of a sinus, and dilatation of a diploic vein (sacciform); perforation of the skull and sinus followed by immediate extravasation of blood beneath one or more of the scalp layers, and rupture of an emissory vein (false).

2. The *varicose* or *erectile* variety is composed of tortuous and varicose veins—principally the emissoria Santorini—in fine or gross bundles, bound together by connective tissue; and, occasionally, of a structure resembling true erectile or cavernous tissue.

Each of these several divisions and varieties will receive additional consideration in the subsequent pages.

CLINICAL RECORDS,² WITH COMMENTS.

A separate review of every individual case of the number collected, although requiring what would appear to be a needless detail and repetition, is really essential in an extended examination of this lesion, especially because of the several varieties of venous blood tumors communicating with the intra-cranial circulation, each of which appears to demand liberal illustration. It shall be my endeavor, however, to make this notice as brief and condensed as the proper and connected presentation of the histories will permit, with a correct appreciation of the different salient and distinctive points which they offer.

I. CONGENITAL CLASS.

The earliest record of any case belonging to the congenital group which has come to my knowledge, is that occurring in the practice of Moreau, and related by M. Pelletau (*Clinique Chirurgicale*, t. 11, p. 76, Paris, 1810) as follows:

"A youth, 15 years of age, had located on upper part of forehead a congenital swelling the size of a pigeon-egg. It became larger and also of a bluish color when he stooped over the table at work, but in the morning upon first awakening it was much smaller and without discoloration.

"M. Moreau divided the tumor centrally, and packed the profusely bleeding wound with lint, but this failing to arrest the hæmorrhage, the surface of the wound was painted with butter of antimony, requiring very many of the cauterizations to control the escape of blood. Now, however, high fever, headache, convulsion, and paralysis of the corresponding half of the body followed, and finally death ensued on the fourth day.

"At the post-mortem examination were found three holes in the frontal bone through which enlarged and dilated veins passed on into the superior longitudinal sinus, thus placing the external varicose

swelling in communication with the intra-cranial venous circulation. For a large area around these perforations the dura mater was inflamed and covered with pus."

Bruns, who also details this observation in full, speaks of it under the heading of *varix verus cirsoideus*.

The next case in point of date is that mentioned by Busch³ in *Heidelberger Klinische Annalen*, t. 11, p. 249, 1876:

"During the accouchement of a patient, after the discharge of the waters (which were thick, greenish and fetid), and whilst head still at superior strait, a large, fluctuating tumor was distinguished on the child's head. The child was still-born; male; weight seven lbs.; skin detached and macerated, and limbs flaccid, showing conclusively that death had taken place some time prior to labor.

On the head there was a rather large, fluctuating tumor, of bluish color, which in length extended from the external occipital protuberance to middle of the sagittal suture, and in the other direction from the point of ossification of one parietal bone to corresponding point on the opposite side, and projected the most in the region of the small fontanelle. All the cranial bones were very mobile, and that which deserves especial note, from an etiological point of view, was the absence of a defined and prominent ring around the border of the tumor. The tumor was opened by a long transverse incision, extending from right to left, which discharged a quantity of dark-colored, viscous blood, of an offensive odor. About two ounces was collected. This fluid was situated between the bones of the skull and the pericranium, and a careful examination of the line of incision showed that several vessels extending across the superior longitudinal sinus had been divided, and that the sinus was in communication with the tumor. The cranial aponeurosis over the site of the small fontanelle was thick and soft, being infiltrated with a gelatinous lymph; this thickness becoming less as the borders of the tumor were approached. This thickness, also, was easily distinguishable from an ordinary tumor of the head. There was no extravasation either in the brain or dura mater, although the cerebral vessels were engorged with blood."

It should be remarked that in Pigné's account of this case of Busch's the lesion is regarded of traumatic origin, being due to the traction and pressure of the forceps employed in the delivery. But this, evidently, is erroneous, for the description given by Busch is so clear and explicit on this point that the intra-uterine death of the child, several days previous to time of labor, is not to be questioned; and hence I must consider the case as one of congenital formation. Dupont also regards it as congenital.

M. Chassaignac (*Thèse sur les tumeurs de la voûte du Crâne*, p. 125, 1848) mentions having heard Professor P. Bérard (senior) relate, during a course of lectures on anatomy, delivered in 1831 or 1832, the history of an infant in whom there was a varicose dilatation communicating with the superior longitudi-

¹ The varicose or erectile variety is not so distinctive of this class of tumors as the other forms, since it is very closely allied to the simple or superficial subcutaneous venous erectile tumors of the scalp.

² For several of these references I must acknowledge my indebtedness to Dr. William Browning, of New York, who very kindly directed my attention to them after the publication of my first paper.

³ Reported also in my previous paper.

inal sinus, and which swelled considerably when the child cried or made any exertion.

This is a simple statement without any careful or decided clinical details, and nothing to indicate its manner of communication with the intra-cranial circulation; but there seems to be no reasonable doubt of its being congenital in formation, and composed, probably, of varicose venæ emissoria.

The case of Flint is thus briefly given by Pigné, Chassaignac, Dupont, and others:

"There was found in the occipital region of an infant, several days old, a tumor of considerable size. He opened it. It contained venous blood, which flowed out in such quantities that the infant speedily perished from hæmorrhage. Examination showed this tumor to communicate with the longitudinal sinus."

From the symptoms presented, and in the absence of contradictory data, this case may be regarded as an ectasia or hernia of the sinus through the posterior fontanelle.

Mersemann records (*Observateur Médicale Belge*, 1834) an example of considerable interest. Bruns also mentions this case, and includes with it that of Moreau's under the head of varix verus cirsoideus, as before referred to:

"At birth a well-formed child had over posterior fontanelle a swelling the size of a pigeon egg, which in the course of six weeks had increased to three times that size. The pedicle was almost as large as the swelling itself; the skin covering it was thickened and wrinkled, although through it could be felt the fontanelle and edges of parietal and occipital bones. The tumor was uneven; no pulsation; color and temperature normal; but it became tense and bluish or even blackish-blue when child made any exertion whereby the blood return from head was interrupted, but not increased in size. Palliation being useless, as the growth continued to increase, and as the mother insisted upon its removal, strangulation of the tumor was undertaken. Hence, whilst child was at the breast, a ligature the thickness of a writing quill was adjusted about the base. Upon the first tightening the child screamed lustily and struggled with hands and feet, but as soon as it was fully tied the infant became quiet, sucked, and fell asleep without indicating further pain. Next day child equally well—the swelling remaining same in size and color. On third day the strangulation had increased without any bad effect, the surface being cold and bluish, with fetid discharge from around the ligature. By the fourteenth day, after repeated tightenings of the ligature, the pedicle was reduced to size of a swan's quill, and, after applying a second ligature thereto, the tumor was ablated without a drop of hæmorrhage. There was now left a simple sore, of good appearance, at base of which the fontanelle could be felt, and in three days more the second ligature separated and the ulcer healed. On opening the tumor there was disclosed a mass of areolar tissue containing a bunch of greatly thickened veins in which were several spherical enlargements (dilatations). The scalp was quite thick, but beginning to shrink."

Stromeyer (*Ueber Sinus Pericranii*, *Deutsche Klinik*, Bd. 11, S. 160; April 13, 1850) reports a case observed by Francke. This is classed by Bruns under the title of varix verus circumscriptus:

"Christian Brandt, a soldier, native of Wenelsfleth, 20 years old, was born with a swelling over left eye, for the dissipation of which medical aid was unavailable. This swelling, according to report, is now, proportionately, of same dimensions as in early life; extends from the glabella two inches to the left, and from the arcus supercilii to three lines above hair margin, covering about four inches square, and when distended is elevated about one inch. When patient is at rest the swelling does not stand out, but exertion, stooping, coughing, sneezing, compression of jugulars, warmth, and all conditions causing the blood to flow to head, or preventing its return, cause the swelling to fill, become tense, and elastic like a distended gland-abscess. When flaccid the skin pale like the walls of a completely emptied abscess. On outer edge of arcus supercilii is felt, through the swelling, a depression in frontal bone, and in this depression towards the external side there exists, apparently, a pretty large foramen. The length of depression is three inches, breadth one and a half to three lines. No pain except when he wears a heavy head-gear, or when making great exertion, under which circumstances there arises swimming of head and a feeling as if tumor would burst. Color of skin unchanged, even under maximum distension. Easily emptied by pressure, and refills in one-half minute. When distended the tumor is equally elastic over entire surface, and clearly outlined. Curative treatment not employed because considered useless and dangerous."

M. Verneuil presented, for M. Michaud, of Louvain, to the Société de Chirurgie, a pathologico-anatomical specimen with this history (*Tumeurs Erectile du Crâne Communiquant avec le Sinus longitudinal Supérieur*, *L'Union Médicale*, 8 Février, 11 Série, t. 1, p. 254, 1859):

"A young man 28 years old with an erectile tumor of superior eyelid. This swelling was without bruit or pulsation; its volume augmented upon compression of jugular vein or when patient stoops forward, but diminishes when head is erect. It is irreducible, and does not present characters pointing to communication with interior of skull; patient experiences sharp pains in tumor, and vision cut off by drooping of lid. Congenital in origin. Operation by cauterization with red-hot iron applied to three points. No trouble at first, but on seventeenth day patient seized with facial erysipelas, which was epidemic, followed by meningitis and death. A few days after operation the patient announced that he had another similar tumor on his head. This presented exactly same characteristics as first one. At the autopsy each tumor showed a cavernous tissue like ordinary erectile tumors; under them the bone was perforated by a multitude of little apertures which gave passage to the vessels penetrating into the interior of skull, thus putting each tumor into communication with the superior longitudinal sinus."

Middeldorff gives the the history of the subjoined

case⁴ in a private letter to M. Dupont (*Essai sur un Nouveau genre de tumeurs de la voûte du Crâne formées par du sang en Communication avec la Circulation Veineuse intra-Crânienne*, p. 26, Paris, 1858):

"Matilda H., æt. 9 years, daughter of a peasant living at Carlowitz, near Breslau; well nourished and developed. From birth there existed on her forehead, a little to left of median line, a tumor covered by the hairy scalp. It is round, smooth, and does not pulsate. Shortly after birth it was the size of a cherry, but now (1851) it presents a diameter of an inch and a half, and one-quarter inch thick. Offers different degrees of tension—one time flaccid, and then again much distended, but there is always a little fluctuation. Bending the head forwards toward the ground, etc., causes it to swell up; deep inspirations make it sink slightly; it quickly and without difficulty disappears under continued pressure, and this does not produce the least symptom of cerebral compression. After reduction the base of the tumor is found to be circumscribed by an edge or ridge three-quarters of a line deep, denticulated, and which felt to be bony by the exploring needle. The base or floor of the tumor is formed by the cranial vault, almost flat, and without the sensation of any opening penetrating it, and is covered seemingly by a thin membrane. There are no cords or filaments to be felt in the tumor cavity except near the skin and hair line, where an ovoid cartilaginous button is perceptible, which is movable and about size of a grain of rice.

"In 1856, at my clinic, I examined this tumor a second time, but, with the exception of being a little larger, it presented the same symptoms; the girl, also, continuing in good health. Pressure upon the tumor, after encircling it with an ivory ring which closely fitted its base, and pressing the ring down sufficiently to cut off the skin circulation, also causes it to disappear, thus demonstrating conclusively that the blood flows from the direction of the osseous base, and not from circumference vessels."

In the *Bulletin de la Société de Chirurgie* (t. iv, p. 414, *et suiv.*) M. Verneuil reports the following case⁵ of this malady:

"A young girl, aged 17 years, of a strong constitution and good health, presented herself to me, in 1854, for advice concerning a tumor on the forehead which had existed from infancy. She had some indefinite recollection of a blow received in early life, but it was entirely too vague to be relied on. No evidence of hereditary trouble in any of the family, and the tumor is, evidently, of congenital origin. The symptoms are as follows: Fluctuating, soft, and round; painless; ordinarily it is of the volume of a large nut when she leans forward, and is situated on the right frontal protuberance. The skull is unaltered in consistency or color, and no vascularity of the surrounding parts. Pressure causes it to sink and disappear entirely, and after reduction one can definitely determine that there is no appreciable alteration of the bone, and only a little circular ridge around it (its limiting boundary) is perceptible. This is rather resistant. The tumor is easily reduced

by pressure, which must be steadily applied, and by this manipulation the sensation of a pouch partially filled with fluid, which empties itself, is experienced. The tumor bulges out under the influence of exertion and emotions, but there is neither bruit nor pulsation; and, again, cough does not affect it. When the head is lowered the tumor becomes voluminous, with the dimensions of 3 cm. in diameter by 1 cm. deep. In the dorsal decubitus the tumor attains a very large size, but it is largest when she sits in the sewing position with the head inclining forward. During the menstrual epochs, however, the tumor assumes, perhaps, its greatest volume, and at these periods she suffers from decided headache, but to this she is, at any rate, subject.

"Later a cure took place, or, at least, the tumor subsided after a very prolonged examination with repeated palpations to which she was subjected at the Surgical Society."

M. Verneuil announces the favorable termination of this case with caution and reserve, because of his inability to verify the permanence of the cure by another examination at a more remote date; as, immediately after the subsidence of the swelling, she disappeared, and was not again seen.

Case of M. Foncteau (Note pour servir à l'histoire des Kystes des Enfants Nouveau-nés; *Gazette Médicale de Paris*, November 2, 111 Série, t. xvi, page 695, 1861):

"A congenital tumor of the cranium, pediculated, situated over the posterior fontanelle. It was of a blackish color, fluctuating, and was divided by a vertical furrow into two unequal lakes. Greatest diameter was transverse; circumference measured around largest part 0^m, 40, and at smallest part, 0^m, 30; pedicle was 0^m, 12. The pedicle was strangulated by a thread, and tumor punctured in right half, from which 300 grammes of a serous fluid flowed out, but only the right half was emptied thereby. Another puncture in left side gave exit to about an equal quantity of a sanguinous fluid. The pouch was not tardy in refilling, and by the following morning it had acquired about one-half of its former volume; but at the same time the child was steadily sickening; lips and surface pale. Death followed. The autopsy demonstrated a communication between the superior longitudinal sinus large enough to admit the little finger. In the principal cavity floated a little accessory pouch, the orifice of which was distinct from the main tumor opening. On right wall of large cavity there existed another opening, of oval shape, with a sphincter-like edge, communicating with a third cyst. This is the cavity from which only the serum flowed. The pouches emptied after death furnished 255 grammes of blood, which, added to the 225 grammes extracted by the puncture, gives a mass of 480 grammes taken from the child in twenty-four hours, which is amply sufficient to explain its death. The pedicle was only incompletely strangulated. The little pouch in the middle was formed, apparently, of the vascular serous membrane. The two other compartments were lined with a very vascular serous membrane, easily detached from the skin by simple traction, and is continuous with the serous membrane

⁴ Reported also in my previous paper.

⁵ Reported also in my previous paper.

of the cerebral sinus through the occipital fontanelle. This, then, is a blood-cyst formed by a hernia of the serous membrane of the cerebral sinus through the unclosed posterior fontanelle."

Under the designation of "Varix Sinus Verus Extra Cranium Congenitalis," Herman Demme describes elaborately in his excellent monograph, "Über Extracranielle mit den Sinus Duræ Matris communicirende Blutcysten" (Illustrated, *Virchow's Archives*, Bd. 23, fol. 48, 1862), a marked example, of which the following is a condensation:

"In February, 1861, I saw the infant son of W., a locksmith of Berne, nine months old, who was born with a swelling on the head, which had resisted all medical treatment. Other physicians had declared it cystic, and therefore benign, but the father was very uneasy on account of having previously lost a child with a very similar growth on back of head. Child's health is poor, and often in his sleep he cries out and carries hand to head as if in pain. Pressure upon the swelling always makes him restless. He is a pale, weakly boy, with ricketty thorax and large abdomen. Head rather small, covered with thick blonde hair, and located thereon in middle of sagittal suture, is a swelling the size of a small apple. It is roundish, upper surface smooth, its outer covering being the scalp, somewhat pale, and sparingly covered with hair. No vessels visible; by transmitted light tumor is non-transparent; resistance equal in all portions; fluctuation in some places, with firmer masses in others. Continuous pressure gradually reduces swelling only in part on account of these firm masses—pressure, at the same time, causing face of child to become livid. Several large veins over upper eye-lid are distinct. Crying, and compression of jugular veins caused tumor to increase in volume and expansion and tension of walls, with a blue color. No essential connection with extra-cranial veins could be demonstrated, circular compression around base of tumor producing no apparent change. No arterial pulsation, though there was a feeble and doubtful undulation movement. This was a synchronous rising and falling upon inspiration and expiration, which was more positively seen by the excursions of an exploring needle inserted therein; and auscultation discovered occasionally and irregularly a rustling and whirring sound. Withdrawal of needle was followed by a few drops of dark-red blood. Base broad and without pedicle or constriction; no appreciable alteration of bone surface, and hence no perforation of skull could be perceived. Electro-puncture would have been employed, but the instrument was not available, and hence non-interference advised.

"May, 1861, death from cholera infantum. Autopsy: Body emaciated. The swelling, which is smaller (on account of absence of circulation), was incised lengthwise, discharging a dark bloody mass. Interior walls covered by different colored coagulum laminæ, both firm and soft, as in an aneurismal sac. In the coagulum covering the base is a funnel-shaped depression into which a fine probe readily passes through an opening therein, for $1\frac{1}{2}$ inches into the cranial cavity. Removing the cranial vault with the

cyst and that portion of dura mater which is adherent to the bone, the brain is found to be anæmic. The superior longitudinal sinus is distended and filled with coagulum, and is considerably dilated at point corresponding to the extra-cranial cyst, and in which the point of the probe, introduced through the cyst, is plainly felt. In right wall of sinus near its base there is discovered a long oval spacious opening, through which the probe projects. Old blood clot, size of a pea, found in cerebellum. The external cyst-wall consists of the normal scalp; and a closer examination of the other layers forming its walls demonstrated seemingly the fact that it was formed by a hernia of the sinus walls through the osseous opening. The scalp moveable and easily raised, and pulling this forward showed that there was a hollow pedicle to the tumor connecting the sinus with the cyst cavity. The pericranium did not enter into the composition of the cyst-coverings, but was intimately attached to the circumference of the bone opening and the pedicle. The bone was somewhat thinned throughout the space occupied by the tumor, more transparent and in a state of rarefaction. The walls of the superior longitudinal sinus were thickened, especially the fibrous elements, but otherwise little altered."

Demme also refers to a similar case, related by Bardeleben at a meeting of the Naturalists, in Speyer. This was in the person of an adult in whom the cyst probably communicated with the sinus longitudinalis. In its treatment, Bardeleben successfully practiced electro-puncture.

Finally, the last instance which I have to mention in the Congenital group is that of Dr. Acland, of Oxford, which is contained in a paper entitled *Cases Illustrating the Formation of Morbid Growths, Deposits, Tumors, Cysts, etc., in Connection with the Brain and Spinal Cord, and their Investing Membranes*, by John W. Ogle, M.D. (*British and Foreign Medico-Chirurgical Review*, vol. xxxvi, p. 212, July, 1865):

"Case 196.—*Blood-cyst beneath the Scalp, Communicating with the Torcular Herophili.*—The patient was a child, age three years, who died of chronic hydrocephalus.

"*Post-mortem.*—Cranium: At the posterior part of the cranium, beneath the integument, was a venous capsule communicating as described below, with the cranial cavity. The brain was greatly enlarged, and the anterior horn of one of the lateral ventricles was distended with serum. The occipital tuberosity was perforated by a foramen, through which a tube of fibrous tissue passed from the torcular herophili, admitting the blood into the subcutaneous venous capsule mentioned as existing at the back of the head."

The morbid preparation illustrating the above history is in the Pathological Department of the New Museum, at Oxford.

II.—SPONTANEOUS CLASS.

The first example of the Spontaneous Class which claims recognition on the score of priority, is from a specimen belonging to the anatomist Jacobi (or Jakobi), and described by Beikert (or Beyckert) in

his *Dissertat, De Nervis Dura Matris, Argentorati*, 1772, S. 33; but concerning which all minute and descriptive data are wanting:

"It was a case where a large swelling was located in the occiput, which was composed of a cyst filled with coagulum. Close examination demonstrated the existence of a rather long hole in the os occipitis through which the superior longitudinal sinus protruded as a hernia under the scalp; and this, from the examination of the preparation, is, without doubt, the result of a secondary perforation, and not the congenital protruding of the sinus through a fontanelle."

Several authors refer to this example as an instance of congenital hernia of the sinus finding exit through the posterior fontanelle; but, as both Bruno and Demme (from the latter of whom I get my information, not being able to secure the original dissertation of Beikert's) claim a secondary origin, and, therefore, a probable non-traumatic perforation of the skull arising subsequent to birth, I have felt warranted in placing it in this division.

In the *Gazzetta Medica di Milano*, Nro. 1, 1843, is found the subjoined case by Giovanni Melchiori:

"In a girl, 14 years old, there was first discovered during an attack of fever with severe headache, a swelling on left side of head, beginning one inch above mastoid process and extending up to middle of parietal base. Transverse diameter below was 12 lines, above, 9 lines; thickness below, 8 lines, above, 3 lines. Surface convex and smooth, but skin thinned in several localities, and of a transparent blue; base not movable; temperature normal; not sensitive to touch; consistency uniformly soft. Patient complains of a deep continued pain, accompanied by a pulsation extending into ear, but ceases when lower part of swelling is compressed. Later there was observed at lower third a simple rising and falling of the tumor synchronous with cardiac pulsations, with a blowing murmur. After death the swelling disappeared, there being in place thereof a network of empty veins, varying from the size of a thread to a pigeon quill, which intercommunicated freely, and finally ended in a common trunk the thickness of a goose quill. This passed through the galea aponeurotica capitis at lower and posterior edge of the parietal bone, piercing the bone, and finally opening into the transverse sinus, where it lies on inner surface of the temporal bone. There was meningitis, and all the cranial sinuses were filled with partially suppurating clots, although there was no disease of the sinus walls."

The following record of Hecker (*Varix Spurius Circumscriptus Venæ diploicæ frontalis*, etc. *Erfahrungen und Abhandlungen im Gebiete der Chirurgie und Augenheilkunde*, Ss. 151-155, with illustrations, Erlangen, 1845), especially illustrates the theory of slight traumatism in the production of osseous atrophy:

"H. G., æt. 34 years; a factory hand; bileo-sanguineous temperament; of habitual good health, excepting several attacks of pneumonia; had on right side of forehead a distinctly fluctuating swelling, appearing gradually after certain movements and exertions, and which could be made to appear and

disappear rapidly. It arose during the first year of life, after repeated blows received on head against a wooden floor in learning to walk. No effect resulted from remedies applied at that time. Notwithstanding the swelling increased with years the patient refused medical aid, because he had become accustomed to the insignificant annoyance which it caused—there being not the slightest mental trouble. For many years it remained *in statu quo*. In 1834 he received a stab in tumor with a pitchfork. Severe hæmorrhage lasting for half an hour followed, but stopped spontaneously; and with the exception of remaining scar there resulted no inconvenience. When fully distended the skin covering becomes dark blue, with little spots of capillary enlargement over surface; it is also painless on pressure, somewhat tense, plainly fluctuating, and can be caused to disappear at once by light pressure of the hand. No bruit. Transverse diameter of the fully distended tumor is three and one-fourth inches; vertical diameter three inches; circumference at base eight inches; height two inches. It occupies almost entire right side of forehead, slightly encroaching upon left side, and consists of two parts, one within the other as it were, irregularly separated by a circular shallow depression; the larger or main tumor being size of an apple, and of blue color; the smaller is less prominent and of normal color, and gradually passes out into surrounding healthy skin. All movements interfering with return of venous blood from the head cause the growth to enlarge, as coughing, sneezing straining, etc., but this enlargement is scarcely up to one-half its capacity, and subsides on cessation of the effort. No effect produced by holding breath. It augments to greatest extent and most rapidly by forward and backward bending of head, deep and continued expiration, pressure upon neck, and especially compression of jugular veins. The filling of tumor by bending head forward is accomplished in two minutes; by pressure upon right jugular vein in one minute; and by pressure of both jugulars a little more rapidly. Although compression of left jugular causes the complete distension of the growth, yet only one-third of the tumor fills rapidly; and generally one-half of the tumor swells faster than the other, which is notably slower in distending. Expansion begins by undulating movements a half inch above orbital vein at the lower and sloping edge of tumor. Only when distension is complete does patient complain of sensation of tenseness and dizziness. If head is now brought erect or if deep inspiration is taken, the swelling disappears spontaneously in the space of a minute, thus subsiding twice as rapidly as it developed. Light pressure effects reduction in ten seconds, and when reduced the walls form a loose, bagging sac, which hangs down one-half inch over brow; and above is distinctly felt occupying the right half of forehead a crescentic depression with horns looking downward. A pulsating vessel is also felt corresponding to the supra-orbital artery, and which causes pulsation of empty sac. More careful examination also discloses a circular opening in external table, of the diameter of two and one-half inches, surrounded by a sharp osseous ring, but this

absence of the outer table is not shown to be a complete perforation through the entire thickness of the skull. Therefore, just beneath the skin lies the diploic structure, on which is plainly felt numerous osseous projections from the size of a lentil to a pea, partly smooth and partly rough, together with depressions or real furrows—apparently the bony canals in which run the frontal diploic veins. About middle of this opening but nearer to supra-orbital ridge, there is a prominent osseous projection, in the point of which there is an apparent opening, and which is painful when roughly handled. Attempts at compression had no effect upon tumor. The growth is, therefore, a cutaneous blood-pouch which communicates by means of the frontal diploic veins with the intracranial venous circulation. Operative interference considered doubtful and hazardous."

Hecker employed this term of "varix spurius circumscriptus venæ diploicæ frontalis" on the suggestion of Stromeyer, who chose the appellation from the analogy which the lesion seemed to bear to circumscripted false aneurism. In a later work (*Deutsche Klinik*, Bd. 11, S. 160, April 13, 1850), however, Stromeyer considers this title inappropriate, both on account of its length and the insufficient designation or description of the actual character of the growth which it conveys. Again, traumatism being, so evidently, a primary causative factor here, this case would appear to belong to the third or traumatic group; but it must be remembered that in the classification adopted, the traumatic class is composed alone of cases resulting from direct cranial fracture or suture separation.

The following, which is the case⁶ of MM. Nélaton and Richard, was presented by Richard to the Société de Chirurgie, Oct. 1, 1856; and was afterwards examined and fully and carefully reported by Dupont (op. cit., p. 28):

"B., laundress, æt. 19; moderate stature and strength; chestnut hair; born at Signier (Mauche); admitted Sept. 22, 1856, to l'Hôpital des Cliniques, bed 4 of woman's pavilion, during the time that M. Richard had charge of the service of M. Nélaton, in the absence of the latter.

"No hereditary trouble in either herself or family. No serious attack of illness except one when 4 or 5 years of age, and and which was evidently some 'sweating fever.' In 1848, when 11 years old, she was seized with a violent throbbing frontal headache, which deprived her of sleep and lasted her the entire night. The day following, the pain still present, and greatly augmented when she assumed the recumbent posture. In arranging her hair on this day she lowered her head, and in so doing discovered that there was a soft point on top of head as large as a five-franc piece. In reply to questions, her mother informed her that it had existed ever since her sickness at the age above mentioned, at which date she first discovered it. Thus it is probably of congenital origin. She is subject to headaches, but which are uninfluenced by the menstrual epochs. Tumor has been increasing since 1853.

"Examination now presents the following characters: It is situated at the summit of occipital region over sagittal suture, at superior angle of the occipital. When head is erect tumor is not visible, and no projection evident to the touch, but when head is carried forward or backward the tumor immediately appears, and is globular and voluminous, with a base of $6\frac{1}{2}$ to 7 cm. in diameter. Uninfluenced by cough or respiration; but any exertion causes it to rise and become apparent, but again subsides on cessation of effort. It is soft and fluctuating; no pulsation or bruit, and artificial reduction not followed by cephalic symptoms. Reduction easy; sensation that of a pouch full of liquid which is emptied steadily and rapidly. Compression of internal jugular veins, even when head is erect, causes a rapid filling of tumor. Circular compression, by string tied around the head, and the jugulars compressed, the tumor appears quickly and to full size. Border of tumor smooth and nearly regular. Palpation shows two or three depressions which might permit intra-cranial communication; curvature of skull unaltered; coverings normal, and without œdema or infiltration. Inconvenience complained of is vertigo, which is produced by stooping or any sudden or extended movements of head. Drowsiness followed manipulation of the tumor. Only treatment adopted was that which would control increase of the growth. Patient now lost sight of until December, 1857, when she stated that she had been pregnant and was then a mother. After accouchement she had an attack of facial erysipelas, accompanied by intense fever and delirium. She had taken no precautions to arrest progress of tumor, and hence it was now found to be modified. These changes are: Increased in all diameters; surface of bone no longer normal in curvature, but is irregular, as if a chip of bone had been raised up from cranial vault, especially at anterior border. In the general depression the finger easily demonstrates four smaller depressions in the bone, two in the median line and one on each side of that line. The median depressions are thus disposed: The first is circular and placed immediately behind anterior border of the tumor, has a diameter of $1\frac{1}{4}$ cm., and admits end of finger pulp. The second median depression is located $1\frac{1}{2}$ cm. behind the first, and has a diameter of $\frac{3}{4}$ cm. only. The left lateral depression is directed from before backward and from left to right, has the form of a cleft of less than $\frac{1}{2}$ cm. in width by 1 cm. long; its posterior extremity extends to within 1 cm. of the median line and to 1 cm. behind first depression. The right lateral depression is on the same level with the left one, but it is circular and is less than $\frac{1}{2}$ cm. in diameter. The anterior median depression has thus modified the external appearance of the tumor, which is now not regularly globular, but resembles the hilus of a kidney. Circular compression does not prevent filling of the tumor; and again closing the four osseous openings with the finger tips, and then inclining head forward, the tumor expanded with same rapidity, showing that there were other unrecognized communicating orifices in the bone.

"January 24, 1858. Tumor now increased in size

⁶ Reported in my previous paper.

on its left side, at which locality a smaller tumor (1½ cm. in diameter) had formed in connection with it, and communicated with the larger tumor."

This case of MM. Nélaton and Richard is considered by them of *probable* congenital formation, but a careful analysis of the history and symptoms given leaves no doubt of its spontaneous origin, and which was the result, in all probability, of a rarefying astitis, due to some trivial blow, about the time of the serious attack of illness in her infancy.

Under the subdivision of "Varix Versus Circumscribitus," already alluded to, Victor Bruns (*Handbuch der Praktischen Chirurgie für Artze und Wundärzte*, Bd. 1, Abth. 1, S. 191, with atlas of illustrations, Tübingen, 1854), mentions an example met with in his own practice:

"A farmer, 36 years old, has observed for the last three years the gradual formation of a swelling on the forehead to left of median line, which is alternately larger and smaller, and sometimes even disappears. He can trace it to no cause. It is entirely painless, firmly located near the middle line in the course of the left frontal vein, which latter, when filled, together with its bifurcation over the swelling, is plainly visible. The tumor is of size of one-half of a hen egg; becomes filled and distended when stooping, as, also, under all conditions interfering with return of venous blood flow from the head; can be instantly reduced by light pressure by the fingers, and when reduced there is distinguished in its site a perceptible depression in the cranium, which on right side is bordered by a padded osseous rim. Pressure upon the venæ frontales below the swelling does not cause its distension, neither does pressure from above prevent tumor from being emptied. (Vide fig. 13, Abth. 1, Taf. iii, of Atlas.)"

In conjunction with this case Bruns details a second instance; but careful examination of this latter one shows it to be simply a cutaneous venous varix with no indication of intra-cranial communication, hence I do not consider it is entitled to occupy a place among the present order of tumors.

In 1855 Dr. John S. Andrews reported a case of "Tubercular Encephalitis with Pulsating Tumor on the Occiput" (*New York Journal of Medicine*, new series, vol. xv, pp. 356-361, November, 1855):

"Lamartine Bovay, born in 1848, of healthy parents. Birth natural and head unusually symmetrical. Mind always active and very bright. Up to age of ten months he was very well, but at that date an eruption, following vaccination, appeared on his face and spread over surface; and as this subsided, dysentery ensued, followed by some pulmonary complication, which, in turn, was followed by glandular enlargements of neck and soreness behind ears, lasting several months. In the ensuing February he was attacked with a so-called intermittent neuralgia, characterized by severe occipital pain, stiffness of neck, and fever, which continued for three weeks. Similar attacks followed up to 1854, when some lung affection again manifested itself. This subsiding, the neuralgic symptoms again appeared, and were severe and erratic. The finale of this was the appearance of a pulsating tumor on back of head, attended by a

gradual loss of sight in left eye. Under treatment, lasting from May to September, his health improved, the tumor disappeared, but no visual change. He remained in tolerable health, except headaches caused by excitement, etc., until May 7, 1855, when another neuralgic attack appeared with same previous symptoms; and about the fourteenth day of this seizure there was slight unconsciousness. He now was extremely prostrated, suffering agonizing pain in back and left portion of head. Veins of head full and enlarged, eyelids closed, pupils sensitive to light but eyes amaurotic. Hyperæsthesia. There was an indentation in occipital bone where tumor had appeared. A few days later tetanic convulsions, lasting several hours, supervened, and shortly thereafter the tumor again appeared, and he died five days later by increasing coma.

"Autopsy—eighteen hours after death. On detaching scalp a number of large distended veins were observed about middle of occipital bone. Just below the external occipital protuberance was found a depression about one-third inch in diameter and one-fourth inch in depth. This was the location of the pulsating tumor, and corresponds with the intra-cranial part known as the *torcular herophili*. Covering this depression in the bone was a membrane which appeared to be formed of the thickened walls of a distended vein, and on incising it venous blood freely escaped. This opening proved to be a complete foramen piercing the bone, about size of a crow-quill, and there was no doubt a free communication between the sinuses of the brain and the enlarged external vein. Brain showed tubercular deposits, effusion in membrane cavities and ventricles, in a word, tubercular encephalitis."

At a meeting of the Surgical Society, held Nov. 23, 1859, M. Verneuil reported the following case in behalf of M. le docteur Jules Dubois, Médecin Adjoint de l'Hôtel Dieu d' Abbeville (*Bulletin de la Société de Chirurgie de Paris*, t. x, p. 238, 1859):

"Case of a Blood-Tumor of the Vault of the Cranium in Communication with the Longitudinal Sinus.—B. (Jean) born at Guer (Morbihan) April 8, 1833, of fine constitution, habitual good health, and without syphilitic manifestations. Belongs to 9th regiment Chasseurs. On May 8, 1859, he applied to be relieved of a wen situated on forehead between eyebrows. An ovoid tumor, about size of a hazelnut, very mobile, soft and pliable to the touch, non-fluctuating, of a slightly violaceous color, occupied the space comprised between the nasal eminence of frontal bone and border of true nasal bones on one side, and between root of brows on the other. No pulsation, no expansion, no rising, no venous varicosities in the vicinity. Light and moderate but continuous pressure caused complete disappearance of tumor, leaving nothing between the fingers but a little core-like substance about size of a lentil, soft and movable. A minute exploration after reduction discloses a thin pedicle which appears to spring from fronto nasal suture, but could not find any communicating opening or appreciable fissure. Compression being removed (patient in upright posture), the tumor returned gradually to its primitive volume.

Reclining on back caused tumor to be diminished four-fifths in circumference; but it augmented and became distended, on the contrary, when the head was inclined forward. Compression and reduction produces no trouble whatever. Interrogated as to the cause and formation of the growth, he said that about five years before he received a blow between the eyes from a stone violently hurled. There was no other symptom besides a thrombus, which disappeared by degrees, leaving, however, for quite a long time a slightly hard swelling, sensitive to pressure, with a heaviness of the head, but without pain. It was only at the beginning of this year (1859) that he felt for the first time a swelling which rolled under the skin. It was now of the volume of a pea, but increased gradually. It produced no trouble whatever, and his only desire to have it removed was on account of its unfortunate location. Accurate and well applied pressure with a roller bandage was totally insufficient, and had to be removed the following day. On May 17 he was sent to the Hôtel Dieu d'Abbeville, that my colleague might see the case. He entered the service of Dr. Vésignié, who also tried continuous pressure by means of forceps applied directly to the tumor; but at the end of forty-eight hours the patient declared that he could stand it no longer; the skin was excoriated, and the tumor had pressed out on either side of the clamps, demonstrating the inefficiency, if not inutility, of such a method. June 18 he returned to his corps, and a few days thereafter I found that the coloration of the tumor was deeper, somewhat increased in volume, and especially that its reduction was not so easy—the dorsal decubitis having little influence over its volume. This was, evidently, the result of the forceps-pressure and the handling, for, at the expiration of a fortnight after being left undisturbed, the tumor presented all of its former characteristics. August 7.—The tumor has progressively augmented in size, now equaling a pigeon egg, skin more thinned, and of a deeper violet color, and from time to time he experiences severe frontal headache, with a benumbing of the senses; tumor turgescient and less reducible. My confrères at the hospital concurred in my diagnosis of a sanguinous tumor communicating more or less freely with one of the sinuses of the dura mater, probably the superior longitudinal sinus. The pouch was evidently not single, but it contained, as shown after complete reduction by pressure, an elastic substance or areolar tissue communicating by a narrow opening with the sinus.

"A rarefying osteitis resulting from the contusion received five years prior to its appearance was, undoubtedly, the cause of this formation. No further treatment was employed, because considered either useless or harmful."

In the *Gazette des Hôpitaux*, October 14, 1856, Baron H. Larrey reports this case:¹

"Val de Grâce, ward 29, No. 10.—O. (Antoine), musketeer of the 8th Line; æt. 23. Entered in September, 1856, with a varicose frontal tumor, the base of which, almost circular, was the size of a five-franc piece, situated on forehead above left eye, partly

within and partly below the hair. He has no recollection of ever having sustained any blow or injury about the head, and he had not perceived its presence until one day, at the age of 11 years, his mother noticed the swelling on his forehead. He was superficially examined by the Army Examining Board, accused of possessing voluntary control over swelling, and declared fit for service, but trial showed that it was impossible for him to wear the shako. At present the tumor is found slightly elevated above the skin-level when patient is reclining, or even standing, but it promptly increases in size when the head is lowered. There are a few ill-defined deep-blue spots on its surface; it is soft, but gives no sensation of pulsation. When sufficiently depressed to feel the bone beneath there is discovered an irregular or stellated perforation of the cranium, and only its shape prevents the easy introduction of the finger therein. Compression causes no pain in tumor itself, but does produce a little pain, with mistiness of vision, in the eye of affected side. Slight symptoms of cerebral compression are produced by pressure upon the tumor. The day of admission to the hospital, after a rather prolonged examination, he was seized with marked vertigo, accompanied by vomiting, diarrhoea, etc. He was declared unfit for military service, and consequently discharged."

At the meeting of the Société de Chirurgie, Paris, October 1, 1856, Middelдорpf referred very briefly to the case of a young girl in whom such a tumor was situated high up in the median line of the occiput, and emptied into the superior longitudinal sinus. This patient was also mentioned by him in a personal letter to M. Dupont (Op. cit., p. 26), in which he stated that, unfortunately, the clinical notes of the case had been mislaid, and hence he was unable to give, with any degree of certainty, from memory alone more than an outline of the case.

M. Giralde, at the séance of July 27, 1864, of the Société de Chirurgie, briefly related the clinical points of this case (*Tumeur Vienneuse, Bulletin de la Société de Chirurgie de Paris*, 2 Série, t. x., p. 357, 1864):

"He presented a child with tumor on frontal region. This growth seems to be formed by the superposition of two osseous fragments. Under the influence of effort, as, for example, blowing into the hands, the tumor swells up; but lightly applied pressure completely reduces it. The consistency is soft; the bending-over posture augments it; and puncture with a pin is followed by the escape of a little venous blood. There is no pulsation. It communicates, probably, with the sinus of the dura. The tumor is of five years duration, and appeared after a fall on the forehead; other than this there is no assignable cause for its origin. A furrow is distinctly felt over the point occupied by the growth, and, the tumor being reduced, pressure by the fingers over this groove prevents its reproduction, notwithstanding those exertions, etc., on the part of the child which usually causes its increase in bulk."

In the discussion which followed the presentation of this case, some doubt was expressed as to the communication of the growth with the superior longitudinal sinus; but the final result was a full concurrence

¹ Reported in my previous paper.

in the opinion of M. Giraldés as to the existence of intra-cranial association.

Again, the length of interval between the reception of the fall and the appearance of the growth is not given, but it is presumable that it did not appear immediately upon, or even a reasonably short time after, the infliction of the injury.

The next example is given by M. Simon Duplay (Tumeur sanguine de la voute du crâne en communication avec la circulation Veineuse intra-crânienne. *Archives Générales de Médecine*, vi Série, t. 29, p. 94, Janvier, 1877):

"A young girl, moderately well-developed, enjoying habitual good health, and having menstruated regularly for the past eight months, presented herself to me at the Hôpital Saint Louis in the month of last August. She was born at term, and delivery of head natural and without interference. At the age of four years the child received a severe fall from the second story, which fractured the right clavicle, but the mother declares that the head was not struck and hence there was no injury to this part. Three years later, however, the child struck her head violently against a table, but the precise locality of the contusion could not be demonstrated. About two and a half years after this second accident the mother discovered, in combing her hair, the existence of a small soft tumor, flattened, situated at the posterior superior angle of the right parietal bone, in vicinity of lambdoidal suture. During last seven or eight months this growth has developed quite considerably, becoming modified in form, and increasing in depth. After shaving the scalp the following particulars were demonstrated: On right side of cranium, in a line uniting the ears in passing over the vault of the skull, at about 10 cm. in front of occipital eminence, there exists a rather projecting tumor, very irregular in contour, with poorly defined limits, of a deep violaceous color, skin-covering thinned, and measuring about 1 cm. from before backwards, and 7 cm. transversely. It continues outwards and downwards on the temporal bone as a prolongation, having the appearance of a large varicose vein, slightly tortuous and baselated, and, becoming greatly lessened in size, terminates in a *cul-de-sac* behind right mastoid eminence. Its entire length is about 2 cm. It is soft, non-resisting, fluctuating, easily depressed, and is incompletely reduced under the influence of very light pressure. The contents are evidently fluid, can be pressed out of the varicose prolongation and *vice versa*; and when the compression ceases the tumor and its prolongation gradually refill. Upon gentle palpation there is perceived a pulsation, very feeble, synchronous with the pulse. These are undulations rather than veritable pulsations, and there is no appreciable expansion. Again, careful and repeated examinations do not discover the existence of any of these vague pulsatile undulations in the varicose prolongation. These undulations, on the contrary, are greatest at the principal centre of the tumor. At the first examination there was heard by means of the stethoscope a faint whirring, intermittent bruit at the centre of tumor, but this could not be verified at subsequent examinations.

Inclining the head forward causes the tumor to augment in volume, becomes very hard, and the child complains of a vague sensation of pain in the head; and the same phenomena are produced with more intensity when the head is strongly bent backwards. The normal respiratory movements do not exercise any manifest influence in the volume and tension of the tumor, but these are slightly influenced by forced expiration with the nose and mouth closed. Upon pressure upon the prolongation, so as to press out its contents towards the principal tumor, causes it to disappear completely, and it is not reproduced upon exertion or forward inclination of the head whilst compression is maintained at its junction with the principal tumor. Whilst this prolongation is emptied in this manner gentle pressure upon the principal tumor by means of the hand easily effects its complete reduction. Circular compression by means of leaden strips, etc., demonstrates the non-connection of the growth with the vessels of the scalp. The cranial wall on which the prolongation rests seems to be absolutely normal. One is compelled to admit that the tumor communicates directly with the interior of the skull or the diploic veins. When complete reduction of the tumor is produced there is felt on the cranial surface a sort of irregularity, which feels like an opening, but this is not certain; however, it is seen that compression applied by two fingers to this locality which resembles an opening, absolutely prevents the refilling of the tumor. When reduction is complete the patient complains of a little pain in the head, but she experiences neither vertigo, giddiness, dazzling, nor roaring in the ears. The tumor is indolent. Active treatment not advised."

The point of notable interest in this case is the peculiar venous prolongation terminating in a *cul-de-sac* behind the mastoid process, and which simulates a tortuous vein. The undulatory movements synchronous with the pulse-beat were due, evidently, to transmitted cerebral pulsations.

The last observation, which completes the series of cases belonging to the spontaneous class, is that of C. H. Mastin, in my previous paper (*Annals of Surgery*, vol. i, No. 4, p. 326, 1885):

"W. D. Penton applied for professional advice Sept. 10, 1881. He is a man 35 years of age, laborer, married, and the father of several children. His own health has always been good, and, with the exception of frequent dull headaches, is still excellent. In appearance, also, he is moderately robust and vigorous. There is no history or evidence of hereditary disease, nor is he cognizant of ever having sustained a severe fall, or any blow or wound about the head. When a youth he contracted a gonorrhœa, and also suffered from a venereal ulcer on the glans penis; but now the closest questioning and examination fail to discern the slightest indication of systemic infection. About five years ago he chanced to feel a small lump or wen-like mass, equal in bulk to a common acorn, on the left and posterior portion of the scalp. This was painless, compressible, disappearing entirely on pressure, but partially redilating on removal of the compressing force, and gave so little trouble as to render its discovery the result of the merest accident.

His attention being once called to the existence of the growth, frequent handling followed, and hence he is able to assert that the tumor gradually enlarged until it attained its present dimensions of a large chestnut, although he is equally assured it has remained *in statu quo* for the past eighteen months. As mentioned above, his only inconvenience is an harassing headache, which is fleeting in character—coming and going—and which he thinks is connected with the tumor, but he is unable to trace a positive or direct association therewith. He is confident, however, that the condition and size of the growth is materially influenced by a hearty meal, the recumbent and stooping postures with the head below the level of the remainder of the body, and after muscular exertion; under all of which circumstances it becomes full, tense, and decidedly augmented in volume.

"A careful examination whilst sitting upright, now reveals only a slight fullness of the scalp in the locality indicated, which readily, though somewhat slowly, disappears upon lightly made pressure by the finger or hand, and leaves in its stead an indentation or depression in the skull, occupying the upper extremity of left arm of lambdoidal suture. This depression is quite perceptible, and is of a triangular funnel shape, being wide at margins (large enough to admit tip of index finger), and gradually narrowing down, apparently, to a single small aperture where it penetrates the bone and emerges into the cranial cavity. When the sac is evacuated by compression, the tegumentary covering is regular, lax, movable, and moderately thin, and through which the surface of the bone is felt to be smooth, and devoid of all perceptible irregularities or roughnesses. Reversing this position, and causing the patient to recline or stoop, with his head hanging down, a round, distinct tumor is found to rise and expand steadily over the site of the indentation. It is soft, elastic, conveying to the touch the sensation of an ordinary hæmatoma or blood-tumor of the scalp, not discolored, and is easily reducible, after the emptying of which the osseous depression is again perceived. Dizziness and vertigo result if this posture, with the head lowered, is maintained for a short time. Pressure causes neither pain nor the least uneasiness—cerebral or otherwise. There is no pulsation or bruit; no appreciable effect produced by the respiratory act; but I find that any interruption to the blood-current through the jugulars increases the tension of the tumor. The surrounding integument is unimplicated, and there is no other lesion of the head. There is disturbed cardiac action, but both heart and lungs are without organic disease. The ophthalmoscope shows the papilla and general fundus of both eyes to be normal, although vessels of the disc are rather small and narrow. Hearing normal. Operative interference deemed inexpedient, and hence only palliative measures of a protecting leathern pad and avoidance of excessive exertion was advised."

Here was conclusively an example due to a rare-fying osteitis originating, in all likelihood, from the resorptive action of a Pacchionian granulation.

(To be continued.)

PARTIAL PARALYSIS OF MOTOR OCULI NERVE.

BY CHARLES W. KOLLOCK, M.D.,

OF CHARLESTON, S. C.

The paralysis of certain muscles supplied by branches from a nerve, while muscles innervated from the same source are perfectly active, has not unfrequently been noted. A case of this nature has recently come under my observation which is thought worthy of reporting.

Eliza Grant, colored, aged about 30, applied at my dispensary for treatment of the right eye on April 17, 1886. Her history was as follows: About five years since she was confined without trouble. Two months later she was suddenly taken sick, had intense pain in head and was unconscious for a month. Upon regaining consciousness the right eye could not be opened. It was fully four months before the lid regained its power, and then very gradually. Electricity was applied a few times by a physician, but a month or more elapsed after its last application before any improvement took place. Since then she has been in good health, but has suffered at times from pain in the eye and head, and especially when sewing, or doing any similar work.

Upon examination nothing peculiar was at first seen beyond an apparent *retraction* of the globe. Vision was $\frac{1}{2}$? (Oliver's test card). While directing patient to follow the movements of the finger in different directions, in order to test the strength of the muscles, it was immediately noticed that when the finger moved in the horizontal plane all movements were normal, but as soon as changed to the vertical the eye (right) ceased to move beyond a slight twitching from side to side. Here was paralysis of the superior and inferior recti and inferior oblique muscles. Further examination showed the pupil somewhat dilated and an inability to read type smaller than Jaeger No 15, which could be seen at 12"—. + 3 D. improved reading to Jaeger No. 6 at 10"—12"—. The ophthalmoscopic examination showed both discs physiologically cupped, media clear, fundi normal and eyes about emmetropic. Distant vision in both eyes was the same—the left normal in every respect and rejecting all glasses.

There are then three muscles, viz.: superior and inferior recti and inferior oblique, paralyzed, with the muscle of accommodation and the circular muscular fibres of the iris partially so—all receiving their nerve supply from the motor oculi. It will doubtless be safe to surmise that the patient had some inflammation and perhaps hæmorrhage near the origin of the nerve at the base of the brain, and that all muscles supplied by it were paralyzed at first, three continuing in that condition, viz.: superior and inferior recti and inferior oblique; two remaining partially paralyzed, viz.: muscle of accommodation and circular fibres of the iris, while the levator palpebræ and the internal rectus are normal in their movement. The third nerve is rarely paralyzed without the levator palpebræ being involved, and this was the case, as is proved by the inability of the patient to elevate the lid for four months.

That the levator palpebræ and internal rectus have

fully recovered, leaving the others still in a paralyzed state, is interesting, and especially since the levator palpebræ and superior rectus are supplied exclusively from the superior division of the motor oculi. Why these muscles should have fully regained their power can only be explained by the supposition that the fibres of the nerve supplying them must have their origin more remote from the seat of disease, and were therefore less affected. There was no history of syphilis, nor were there any symptoms of such trouble. Large doses of iodide produced no change, nor is it thought electricity would be beneficial after so long a period of inactivity and no improvement following its use before. The apparent *retraction* of the globe is of interest from the fact that the opposite condition usually accompanies paralysis of the motor oculi, on account of the relaxed state of the orbital muscles.

Charleston, S. C., July 15, 1886.

MEDICAL PROGRESS.

ON LESIONS OF THE CORNEA FOLLOWING THE INSTILLATION OF COCAINE.—Numerous instances have now been recorded in which the use of cocaine has been followed by local ill effects: These may be divided into two classes, namely, suppurative panophthalmitis and lesions of the cornea. The former being in all probability, due to septic infection, cannot be said to depend directly upon the use of cocaine, except in so far as cocaine increases the absorbent properties of the cornea (a subject that will be considered presently) and direct inoculation occurs from impurities in the solution used.

The corneal lesions which have been observed are of two kinds; (1) an affection of the epithelial layer only, consisting of vesication or desquamation, and (2) interstitial opacities, often taking the form of a kind of striated keratitis extending from the wound.

One of the first to observe the superficial changes was Paul Bunge (*Klin. Monatsbl. für Augenheilk.*, 1885, p. 402), and very many instances have been recorded since. In some of these, the case has not been complicated by the employment of any antiseptic solution, a point which, as will presently be seen, is of considerable importance. There can, therefore, be no question that the vesication and desquamation which occasionally follow the use of cocaine are really due to the action of the drug.

With the view of ascertaining how cocaine produces this effect, Würdinger has recently conducted some experiments upon animals (chiefly rabbits, but also upon dogs and guinea-pigs) (*Klin. Monatsbl. für Augenheilk.*, April, 1886). In addition to the anæsthetic action of cocaine, one of its most marked effects is the dryness of the surface of the eye which it causes; this is probably due chiefly to the anæmia of the conjunctiva and the diminution in the lacrymal secretion from constriction of the blood-vessels; but it is probably increased by the wide opening of the palpebral fissure that usually occurs, and the absence

of the natural and involuntary blinking movements.

In order to ascertain how far the changes in the corneal epithelium were due to these causes, Würdinger instilled a drop of a 5 per cent. solution into both eyes of a rabbit, at intervals of four minutes. The one eye was kept closed between the instillation, but the other remained open.

In the closed eye no changes whatever took place in the appearance of the cornea. In the other eye, after three or four minutes, slight changes were noticed; these increased, and, in twenty to twenty-five minutes after the cocaine had been commenced, the cornea presented a superficial and fine roughness, as well as depressed areas, which looked as if they were caused by the shedding of the epithelium. After an hour, the turbidity of the cornea had increased so much, that the condition of the iris could no longer be made out.

Further experiments showed that the intensity of the changes depended more upon the duration of the experiment than upon the concentration of the solution, or the frequency with which it was applied. By dropping distilled water upon the cornea, between the applications of the cocaine, changes which had already occurred were not removed, but their increase was prevented. Microscopic examination of the altered areas showed that the epithelium, were not removed, was thinned out, and that there was also considerable thinning of the anterior layers of the true corneal tissue.

As regards the interstitial opacities of the cornea, Dr. Wood-White (*Ophthalmic Rev.*, Jan., 1886, p. 6) appears to have been the first to suggest that they were due, not to the cocaine itself, but to the simultaneous employment of a solution of corrosive sublimate. He states that he has frequently used cocaine alone, and in conjunction with boracic acid, and has never seen any ill-effects arising from it, but that in the only cases in which he at the same time used a solution of corrosive sublimate (five cases of cataract extraction), a pearly-white opacity, extending from the wound, was visible on the second day; this cleared up completely in all the cases in a few days.

Dr. Wood-White has omitted to state the strength of the solution of corrosive sublimate used by him, and also whether he has used the same solution alone in other cases; but, assuming that the solution was of the strength ordinarily employed, the conclusion seems a reasonable one that the effect produced was in some way dependent upon the combined action of the cocaine and corrosive sublimate; and some of Würdinger's experiments appear to support this.

Dropping fluoresceine into a cocaineized and into a non-cocaineized eye at the same time, Würdinger found that in the non-cocaineized eye only the superficial layers became fluorescent, but that in the cocaineized eye the deeper layers also became affected. When the epithelium was removed from a limited area, and "methyl-blau" was dropped upon the abraded surface, it alone became colored in the non-cocaineized eye, while in the cocaineized eye the coloring matter extended through the whole cornea. It seemed clear, therefore, that the effect of the cocaine was to increase the absorbent power of the cornea.

Finally, Würdinger found that weak solutions of boracic acid, corrosive sublimate, and even of common salt, which in the normal eye were perfectly innocuous, in the fully cocainized eye produced a turbidity of the cornea, identical with the early stage of the striated keratitis which sometimes follows cataract-extraction.

If subsequent experiments should verify these conclusions, it is evident that the views at present held as to the advisability of employing corrosive sublimate as an antiseptic will have to be considerably modified. It is of the utmost importance that these investigations should be carried further, in order to ascertain what is the weakest solution of corrosive sublimate capable of producing the lesions described, and the weakest that is efficient as an antiseptic. In the meantime, steps should be at once taken to ascertain whether any interstitial lesions of the cornea have ensued when cocaine has been used alone. It is significant that most of the reported cases have been furnished by institutions in which corrosive sublimate is used as a matter of routine; but in many instances it is not stated whether it was actually used or not, the point not being considered of any importance at the time of publication.—*British Medical Journal*, August 7, 1886.

NITRIC ACID IN TESTING FOR ALBUMIN.—DR. E. H. TROWBRIDGE, in a note on "A Simple Method of adding Nitric Acid to Urine in Testing for Albumin," says: We must bear in mind that the specific gravity of normal urine ranges from 1.015 to 1.022, though some authors place it as low as 1.005 and as high as 1.030. Now the specific gravity of nitric acid (U. S. P.) is 1.420, and dilute nitric acid (U. S. P.) is 1.059, each being greater than that of normal urine. To test the urine for albumin, pour into a test-tube of medium size enough urine so that there shall be a column 2 or 2½ centimetres in height; then with a pipette or small tube take up a column of nitric acid 3½ centimetres in height, or, in general, let the column of nitric acid be a little higher than the column of urine (so better to notice the displacement of the fluids). With the finger firmly pressed against the upper end of the pipette or tube, pass the latter to the bottom of the column of urine, still keeping the finger pressed against the upper end; the fluids will mix according to the force of their specific gravity—i. e., the nitric acid will gradually flow to the bottom of the test-tube and the urine will rise in the tube to the height at which was the nitric acid. By this method we can more easily and more clearly notice any turbidity which may be formed, and without any agitation of the fluids. The same method can be followed in using acetic acid (U. S. P.), which has a specific gravity of 1.048, or the glacial acetic acid, which has a specific gravity of 1.056–1.058.—*Medical News*, Aug. 28, 1886.

PUERPERAL TETANUS.—DR. W. NETZEL mentions in the *Hygieia* a case of puerperal tetanus. The patient was a woman of 25, a primipara, who was brought to the lying-in hospital by a midwife a day and a half after labor had commenced. The foetus

was dead, and its large head locked in the pelvis. The os uteri was 5 centim. in diameter, thick and rigid. Perforation was resorted to. The foetus and placenta were expelled spontaneously five hours later. The cavity of the uterus was washed out with a 3 per cent. solution of carbolic acid. The temperature rose on the fourth day and the lochia became putrid. Intra-uterine injections of a 3 per cent. solution of carbolic acid were used, and the vagina was washed out with sublimate. On the eighth day trismus and stiffness of the neck appeared. The following day there was stiffness in the shoulder and spasmodic contraction of the facial muscles, with painful spasms. The temperature was 41° C.; pulse 140. The woman died at mid-day. Chloral had been given and subcutaneous injections of morphia and curare. On making a post-mortem examination, an ulcer was found in the cervix reaching through the uterine walls to the peritoneum. There was parenchymatous degeneration of several organs. Dr. Netzel considered the tetanus in this case to be a symptom of general septic infection.—*The Lancet*, July 31, 1886.

HYDRASTIS CANADENSIS IN UTERINE HÆMORRHAGE.—Some doubts having arisen as to the propriety and the entire safety of using this drug in cases where it is desirable not to cause contractions of other muscular structures than that of the blood-vessels, in consequence of Fellner's having reported that it caused uterine contractions in some of the lower animals, PROFESSOR SCHATZ has investigated the question (*Berl. klin. Wochen.*, 1886, 19), and does not find that it produces any such effect in the human subject. He concludes, therefore, that hydrastis is especially useful in hæmorrhages due to myomatous growths in cases in which their forced expulsion from the uterus would be likely to be attended with evil consequences; in relaxation (eccentric hypertrophy) of the uterus where, after the removal of its contents, it becomes baggy, thus favoring a renewal of the bleeding; in all cases of hyperæmia of the genital organs in which either ergot does not suffice to cause contraction or the alternation of contraction and relaxation serves only to increase the hyperæmia; in cases of acute or chronic pyosalpinx, in which it is important to diminish the hyperæmia without provoking contraction of the tubes; and in chronic peritonitis, oöphoritis, etc. It cannot be replaced by digitalis, since the latter acts unfavorably on the digestion.—*N. Y. Med. Jour.*, Sept. 4, 1886.

MODIFIED CHLORODYNE, prepared according to the following formula, is used by DR. MÉNIÈRE after violent uterine hæmorrhages and in acute painful affections of the uterus:

Chloroform.....	2½ drachms.
Ether.....	75 grains.
Alcohol.....	2½ drachms.
Morphine hydrochloride.....	¼ grain.
Hydrocyanic acid (1 to 10).....	75 grains.
Tinct. of cannabis indica.....	75 "
Glycerin.....	750 "
Essence of mint.....	5 drops.

—*N. Y. Med. Jour.*, Sept. 4, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When remittance is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

IS LIFE WORTH SAVING?

Such is the question asked and somewhat briefly discussed by DR. CHARLES L. DANA in *The Forum* for September. It is not unlike the question propounded a few years ago, and learnedly discussed in a book—"Is Life worth Living?" the obvious answer to which was that it depended on the liver. "Addison once said," says Dr. Dana, "that man should take more care for the direction of his life than the preservation of it. We of this century are inclined perhaps not to reverse Addison's sentence, but to lay much more stress on the question of preservation." Addison should have shown how a life could have direction without being preserved, but he did not.

When the question "Is life worth saving" is asked, the question immediately arises, "Whose life?" And from this arise many other questions, such as the value of the particular life, the cost necessary to save it, whether it will not cost a more valuable life to save the particular one. These are questions for the individual, not for nations and governments; these must look to the preservation of every life, at whatever cost, of however little apparent value it may be. Modern medicine, surgery, and sanitary science have shown conclusively that life can be saved, that years and years may be added to human life as a whole. It is almost impossible to estimate the years saved to human existence by vaccination alone, by ovariectomy, by quinine. "Compared with a century ago, although no particular individual reaches any greater age, the average duration of life has doubled. English statistics show that since 1861 the decreased death-rate adds 2,000 years to the lives of

1,000 males, of which years seventy per cent. is passed between the ages of twenty and sixty, the productive period." And suppose we look at the economic value of life-saving. Sir James Paget has estimated the value of a child's life at \$200. "It costs an average of \$500 to raise a child. Its death at the beginning of the productive age is, therefore, so much lost. The value of an adult life to the State is placed at \$750 (Farr's estimate, which is very low), and its annual productive power at \$95." We may now estimate that about one-half of all deaths occur during the productive age. The annual deaths in the United States, during this age, is about 400,000. It is easily seen that a small per cent. reduction of this death-rate would mean a very large amount of money. This is still more clearly seen when it is remembered that every death represents about two years of sickness, and that in this country there are about a million and a half persons sick all the time, or thirty-six million sick for one month every year. "In England and Wales, it has been found that every working man averages a week and a half of sickness in the year. Rochard estimates that the annual wage-loss to France from sickness is \$70,000,000, the total loss \$141,000,000, and the loss from death \$188,000,000." The actual loss from sickness is then immense. We have reason to believe that any means which will lessen the death-rate will lessen sickness to a corresponding degree. "The economic opportunities in this direction are, it is believed, still very great; and we are assured that the death-rate can in time be reduced from the present average of 20 per 1,000 to 10 or even 5 per 1,000, while the amount of sickness ought to be reduced nearly one-fourth, or from 200 per 1,000 to 60 per 1,000."

While it might require some time and research it would not be a difficult task to show that human mortality and sickness have been diminished within the past ten, twenty, or fifty years, and some of the means by which this has been accomplished have been already indicated. In one of the largest hospitals in this country (Bellevue) the percentage of deaths to admissions was twenty per cent. for forty years; but it is now about ten or twelve. In the ninety years from 1741 to 1827 the proportion of cures to deaths in St. Bartholomew's Hospital increased fivefold. For thirty-six years the death-rate from consumption has steadily decreased. Since Lister showed that perfect cleanliness was essential in surgical operations, only a few years ago, the number of years saved to human existence, and the number of years saved to individuals by diminishing the time of sickness is enormous. The mortality in

childbed has also been reduced from a percentage of one in twenty to one in two hundred (in public institutions); and this, it should be remembered, is a disease which selects its victims from the productive period of a woman's life. Who can estimate the amount, in life and money, in days of sickness, that have been saved by such efficient bodies as the State Boards of Health of Michigan, Illinois, and Louisiana? They stand between the people, of their own and other States, and the list of preventable diseases, some of which are so fatal. The late epidemic of small-pox in Montreal is a dreadful example of the neglect of a government in its proper duty to its citizens.

There is, however, another side to this picture. While what are recognized as preventable diseases are less frequent and less fatal than formerly, while miasmatic diseases formerly stood at the top of the list, it seems to be a fact that local diseases are now more prevalent and more fatal than ever before. But the so-called local diseases cannot all be classed among the non-preventable disease. Diseases of the heart and lungs, nervous diseases, cancer, diabetes, syphilis, renal diseases, idiocy and insanity, and diseases from alcoholism while doubtless more frequent or more fatal than formerly, are in a great number of cases, in a very large percentage of cases, preventable. Fewer persons have consumption, and more get well; and there is thus a larger percentage of tainted survivors to propagate the diseased tendency to offspring. There seems to be an undoubted increase of the defective classes; an increase in the number of still-births, and in the number of suicides; but we must consider very many of these as due to distinctly preventable causes. Of course the great question in many cases is how to prevent them. Some of them, in the existing state of society, cannot be prevented at present; others can only be prevented by the making and enforcement of rigid laws. Should the day ever come when there will be strict laws against the propagation of syphilis, against the marriage of defective and alcoholic persons, then we may look for a great decrease in the number of local and nervous diseases. When the day comes, as it must, when people will recognize and obey the laws of health in education and life, there will be a large decrease in the number of nervous cases, and there will certainly be a decrease in the number of still-births.

"Is life worth saving?" We cannot give a better answer than Dr. Dana has given. "Life is worth saving because it represents something divine and immortal; and it ought to be saved and cared for at every cost, no matter how wretched or insignificant.

To do this will not pay in money, but it is society's moral discipline, and the reward is a spiritual enrichment. It is not enough that society cannot afford to be cruel, or that it, as a utilitarian measure, must put a high value on the life of its members. Our ideas of cruelty are relative. They were not all bad who watched the gladiators, and who knows how soon we might become insensible to the fact that our loads of vice, deformity, and hopeless suffering were scientifically and inexpensively removed? In fine, life is only worth saving because it represents more than mortality; and only from this higher and spiritual stand-point can preventive and curative medicine in all its applications be justified."

COMPENSATION OF MEDICAL EXPERTS.

An interesting paper on this subject was read before the Chicago Medico-Legal Society, on September 4, by DR. MARSHALL D. EWELL, the well-known medico-legal attorney. The subject is one of practical interest to medical men, and it may be well to note the statutory provisions bearing on the question in some of the States.

In Iowa "Witnesses called to testify only to an opinion founded on special study or experience in any branch of science, or to make scientific or professional examinations, and state the results thereof, shall receive additional compensation, to be fixed by the court, with reference to the value of time employed and the degree of skill or learning required." Similar provisions may be found in the statute books of North Carolina, Rhode Island and Minnesota. In Indiana experts are compelled to testify to an opinion without extra compensation. In conflict with this is a decision of an Indiana Court, based on the clause in the Indiana Bill of Rights which provides that "No man's particular services shall be demanded without compensation." In Alabama it has been decided that a physician, like any other person, may be called to testify as an expert in a judicial examination, whether it be civil or criminal in its nature, without being paid for his testimony as for professional opinion; and that upon refusal to testify he may be punished as for contempt. This is about equivalent to a Government compelling a chemist to make analyses in suspected sugar-import frauds without paying him more than—say two dollars a day. The U. S. District Court, Western District of Arkansas, refused to punish as for contempt a physician who refused to testify unless first paid a reasonable compensation.

A Court of Appeals in Texas decided in 1879 that while a physician cannot be compelled to make

an autopsy, yet, having made it, he may be compelled to testify as to the results of his examination. This is only right; but ought a Court to compel him to give his *opinions* as to the case without compensation? In 1884 an Illinois Court fined a physician as for contempt for refusing to answer a hypothetical question in a case of assault and battery. The Court did not go beyond the case in question in the opinion, and might rule differently in another case. In criminal cases, or in any cases in which they testify as to facts that have come within their own knowledge, physicians stand upon the same basis as ordinary witnesses, and are only entitled to the ordinary witness's fee. It would probably be held by almost any Court that a physician cannot be compelled, in order to get his opinion without extra compensation, to examine an insane person or make an analysis of a stomach. It would also be unreasonable to compel a physician to attend an entire trial in order to hear testimony upon which to express an opinion, without extra compensation for his time, if not for his opinion.

We may conclude by quoting from a speech made by Hon. Emery Washburn before the American Academy of Arts and Sciences, in 1866: "If the case be one of a public nature, involving the question of a crime of magnitude, where the public safety requires the investigation, the right to compel the attendance of such witnesses becomes an incident to the exercise of government itself, in the same way that a juror is obliged to sacrifice convenience or profit to render a public service; or the soldier is called upon to take up arms in defense or execution of the law. It rests upon the maxim *salus populi suprema lex.*" But if the State may employ extra expert legal counsel, at extra compensation (as in the late Anarchist trial), why should the State refuse to pay a *medical* expert for an important opinion. Mr. Washburn quotes approvingly the following: "There is also a distinction between a witness to facts and a witness selected by a party to give his opinion on a subject with which he is peculiarly conversant from his employment in life. The former is bound as a matter of public duty to testify to facts within his knowledge. The latter is under no such obligation; and the party who selects him must pay him for his time before he will be compelled to testify."

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

This Association will convene in Toronto, Canada, on October 5, and will continue in session four days. The American Public Health Association is now per-

haps the largest scientific organization in this country, and is still growing rapidly. At this, the fourteenth annual meeting, a large foreign delegation, including thirty representatives from England, is expected. The meeting in Toronto will thus be largely of an international character, as is the Association now, it having extended its working territory so as to embrace the Dominion of Canada. At the last annual meeting, held in Washington, a new "Section of the State Boards of Health" was created, and at this meeting a day, or a portion of a day, will be devoted to the exclusive consideration of matters relating to State Boards of Health. The subjects for discussion at this meeting embrace a variety of topics, such as the "Disposal of the Refuse Matters of Cities and Towns," "The Condition of Stored Water-supplies, and their Relation to the Public Health," "The Best Means and Apparatus for teaching Hygiene in the Public Schools," "Sanitary Experiences in Connection with the Exclusion and Suppression of Epidemic Disease," and the subjects for the Lomb Prize Essays will be included in the general discussion: "The Sanitary Conditions and Necessities of School-Houses and School-life," "The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the Best Means and Appliances for Preventing and Avoiding them." These are subjects of great importance to the public health, and it is to be hoped that much good will come of a thorough discussion of them by the members of the Association and the foreign delegates. Quite a number of papers have already been promised on these subjects by sanitary writers.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, June 9, 1886.

VICE-PRESIDENT, WM. H. TAYLOR, M.D.,
IN THE CHAIR.

T. E. MCARDLE, M.D., SECRETARY.

DR. E. CARROLL MORGAN presented two

SPECIMENS OF MUCOUS POLYPI OF THE NARES,

which he had recently removed, and remarked that the growths were of unusual interest on account of their enormous dimensions. The first case was a gentleman of 28 years, in whom the polypoid mass, which was the size of an apricot, occupied the posterior extremities of the inferior and middle turbinated bodies of the right naris.

The polypus was in immediate proximity to the

pharyngeal orifice of the Eustachian tube, causing annoying tinnitus aurium and partial deafness on the right side. The admirable snare recently introduced by Dr. Hartman, of Baltimore, was the instrument employed in removing the polypus, which came out in two sections and at one sitting. The attachment was touched with the galvano-cautery blade at a cherry-red heat.

A fact worthy of mention is that this patient, who had long suffered from violent bronchial asthma, found great amelioration of and greater freedom from asthmatic seizures after the extraction of the polypus. The tinnitus and deafness have entirely disappeared.

The second patient was a sturdy farmer of 50 years, who came to Dr. Morgan's office that morning from Upperville, Farquier Co., Va., complaining of occlusion of the nostrils of ten years duration. Examination demonstrated slight deformity of the nose and a condition of the nares truly peculiar, for they were so full of polypi that the latter protruded through the anterior nares in front and the naso-pharyngeal orifice behind. There was great intra-nasal pressure, due to the presence of the tumors, loss of smell, impaired sight and hearing, as well as severe occipital and frontal pains.

The snares of Hartman and Douglass were used in operating, and a mass of mucous polypi weighing three ounces, extracted in sections at one sitting, nasal respiration being restored, and little blood having been lost. The galvano-cautery will be used in this case also, and the nares washed daily with the tinctura opii crocata (Phar. Germ.) diluted with water.

Dr. Morgan said that the second case was of interest from the fact of the great number and large size of the mucous polypi removed at one sitting. He had occasionally extracted forty or more distinct nasal polypi from one patient, but had consumed weeks in the undertaking.

DR. J. TABER JOHNSON presented a

MASS FROM THE CERVIX UTERI.

Miss A., white, aged 23, came to me from Emmettsburg, Md. May 25, and gave the following history: Her menses began at the age of 14, and until three months ago were perfectly natural. In March last she began to have severe bearing-down pains and hæmorrhages. She consulted her family physician in Emmettsburg, who, fearing it might be cancerous, took her to a distinguished surgeon in Baltimore. He examined her in his office and told her she would have to go to "the Infirmary" for an operation. This examination caused pain and considerable hæmorrhage. She declined to go to the Infirmary, and came with her mother to Washington and consulted me on the above date.

Upon examination I found a soft, spongy mass, about the size of a hen's egg, growing from one side of the cervical canal, which bled easily and profusely on pressure, but gave her no pain except at her periods, when there was much bearing dysuria and backache.

Upon my advice she entered a private room at Providence Hospital, and twelve days ago I removed

this mass, with the assistance of the House Physician, who gave the ether, Dr. T. C. Smith, and a medical student.

An inverted V-shaped opening was left after all the diseased tissues had been cut away, which I closed with sutures much as one would close the lips of a lacerated cervix. To preserve a patulous canal and as I passed a tent of coarse cloth soaked in carbolized oil into the canal high up, and left it protruding a quarter of an inch into the vagina. No symptoms followed the operation. I removed the sutures on the tenth day and found union perfect. A sound passed readily through a good os and cervical canal. The only point of interest attaching to the case is in its diagnosis. All who saw it previous to the operation thought it to be epithelioma, and she was advised by one physician that her case was hopeless, as nothing could be done which would permanently benefit her.

The following microscopical opinion gave me much pleasure, as the patient is a beautiful woman and engaged to be married:

"The specimen taken from neck of uterus is *not* malignant. I would call it an *adenoma* starting from mucus glands of neck. In fact, it does not amount to much more than an hypertrophy of those glands.

"W. M. GRAY, M.D.,

"Microscopist Army Med. Museum."

DR. JOHNSON also presented a

SPECIMEN FROM AN OÖPHORECTOMY.

Miss C., aged 19, white, the daughter of a farmer in Montgomery Co., Md., came to me upon the recommendation of her physician in the county, Dr. Carraher, and of Dr. Kleinschmidt, her consulting physician in this city. I saw her first in October, 1885, when Dr. Frank Baker brought her to my office for examination, with especial reference to ovarian disease. I discovered none at that time and recommended no operation. Dr. Baker understood from statements of the patient and her family, that she had spasms from infancy. They, however, occurred during the week preceding and at the time of her periods, and for a few days subsequent to the flow—two weeks out of each month—yet I did not detect the ovarian influence in her case and recommended a continuance of the bromides. I am informed by Dr. Baker and Dr. Kleinschmidt that they both succeeded in keeping her free from convulsions, one for nine weeks and the other for eleven, by the use of very large doses of this drug, taking, the girl told me, as high as 300 grains a day for some time.

Her condition was such while under its influence as to make her convulsions preferable. Most of the time when "sufficiently drugged," as they termed it, to keep off the spasms, she was so stupid and helpless as to be compelled to keep her bed, and her cerebral functions were so clouded as to make her for the time little less than idiotic. After going on in this way for six months longer, the young lady finally rebelled, and refused to take more medicine, and demanded, if there was a surgical operation which offered any hope of relief, that it should be performed, and this chance given her to get well. She preferred

death to her present uncertainties and sufferings. She was sent to a private room in the Providence Hospital and I had her under careful observation for about a week, when I determined to comply with the earnest solicitations of her mother and herself, and remove her ovaries and tubes.

There had evidently been a wrong impression about the time when the spasms began, and that they were and had been a true epilepsy from infancy. The following is the history of the case given to me by Mrs. C., with the full knowledge that it was to influence my mind as to the propriety of this operation, and that if the facts were misstated a fatal error might be the result. Mrs. C. stated that the doctors and all persons were mistaken who believed that her daughter's spasms had originated in childhood, and continued ever since. The facts are as follows: She had a spasm when she was ten days old, no one knew why. She had no more until she was three years old, when an attack of pneumonia was ushered in by a spasm. She had no more until she was between 12 and 13 years old, when they began to occur at monthly intervals, accompanied by pain in the head, back and uterine region. Her physician told them that her menses were about to appear and that she would be better as soon as they were established. She had her first period when she was 14 years and 5 months old. The spasms were aggravated and the pains increased at her periods. This state of things has continued from that day to this uninfluenced by medicine, except as stated above, although, to use her mother's expression, she has taken "gallons and gallons and gallons of it," and now positively refuses to take any more. With this statement written out and read to Katie, who confirmed it, as far as her memory went, I concluded to operate.

I believed her case to be one of menstrual or hysterio-epilepsy. I was more ready to accede to the wishes of the patient and her mother since I had read the address of Dr. Gordon, of Portland, to the American Medical Association, as Chairman of the Section on Obstetrics and Gynecology. Dr. Gordon reported twenty-five cases of otherwise incurable or uncured cases of prolonged hysteria, treated by Tait's operation, and a cure was produced of the most dreadful and painful symptoms in all his cases but one or two. Women who had been great burdens to their friends and to themselves for years were by this operation restored to lives of usefulness and happiness. With this report before me I felt, although this was a new departure in the treatment of hysteria, that I had sufficient precedent to operate in this case.

On the 27th of May I removed her uterine appendages in the presence of Drs. Kleinschmidt, T. C. Smith, Carraher, Cuthbert, the house doctor, and a medical student. I found in the left ovary a cystic tumor about the size of a small hen's egg. There were cysts in both ovaries. The large cyst was ruptured in its removal. It appears smaller now than when removed, owing to its having been in alcohol for nearly two weeks. The patient has made a perfect recovery so far, and was to-day, the twelfth since the operation, up and dressed and visiting in the rooms of other patients. She had no pain nor rise

of pulse or temperature above 100°, and took no medicine. Sutures were removed on the ninth day and union found perfect.

I have received the following letter from the mother of the patient, which I append to the history; also the report of Dr. Lamb, Pathologist of the Army Medical Museum:

"DR. JOHNSON:—My daughter has been treated by eight different doctors for six years, and never derived any benefit from the medicine they gave her. She has taken, not pints of medicine, but gallons, and I believe I would be safe in saying a barrel. She has taken it until it has nearly destroyed her mind and greatly affected her throat. She grew worse every year. The operation that was performed I fairly understood, for death would have been a great relief to her, and I am perfectly happy at her present condition, and so is she. * * *

Ovaries and large part of each Fallopian tube. Right ovary 1 3/8 inches in diameter, 3/8 inch thick; contained a number of small cysts and one large one. Left ovary converted into two cysts respectively 3/4 and 1 1/4 inches in diameter.

DR. T. C. SMITH said he had some knowledge of this case before it came under Dr. Johnson's care. The patient had been, he believed, under the care of a homœopath, and, of course, had not improved. Dr. Smith would ask Dr. Johnson the following questions: Was there any uterine displacement? Was there stenosis of the cervical canal? Were the ovaries felt on bimanual examination? What treatment was pursued before resorting to a surgical operation of such magnitude as the one performed? May not an ovary be healthy and yet full of small cysts? Are there not cysts which are not pathological? Was the normal stroma of the ovaries destroyed in part or whole? What per centage of Dr. Johnson's cases have recovered from the symptoms for which he operated? Dr. Smith contended that it is not proper to take any man's *ipse dixit* as to treatment. Dr. Johnson should have kept the patient under his own observation for some time. Dr. Smith read extracts from various reports going to show that ovaries removed by normal oöphorectomy gave no indication of the cause of prevalent symptoms, and that these ovaries differed in no respect from ovaries found in women who had died from various causes and who had not complained of ovarian symptoms. He said that a woman might have large cysts of the ovary and yet complain of none of the symptoms described by Dr. Johnson. Dr. Smith did not wish to be understood as saying that the uterine appendages should not be removed when a woman suffered from hydro-, pyo- or hæmato-salpinx, or where there was a displaced ovary which could not be returned. He thought, however, that it was time to call a halt when young women were being spayed in great numbers, and yet when the ovaries are removed they show no indication as a cause of symptoms.

DR. KLEINSCHMIDT said the patient came under his care two years ago. He and others had tried every drug that had ever been given for hysteria. When the interval between the attacks was increased,

the violence of the attacks was increased. He had once kept off the attack for nine weeks. He had told the patient's mother that there was only one remedy remaining, and that was removal of the ovaries. This was refused, and then the case passed from under his care. She was then treated by Drs. Carroher and Baker until she finally refused to take any more medicine. She was reduced almost to a state of idiocy. Eventually she consented to go to Providence Hospital and permit Dr. Johnson to remove the ovaries. If there ever was a case demanding surgical treatment, this was one, in his opinion. In his examination of the patient he had not discovered any stenosis of the cervical canal, or any displacement of the uterus. There is nothing new in saying that an organ only partially diseased may continue functioning. The history of the convulsions in this case is not clear. He is not certain whether they dated from infancy or puberty.

DR. JOHN B. HAMILTON said that two weeks ago yesterday he removed the ovaries of a patient 18 years old. She had suffered from convulsions since puberty. She had been treated on the Pacific coast and also here in Washington. The intervals between the paroxysms became shorter and shorter despite all efforts. For several months he had treated her most attentively and carefully, and during his recent absence she was under the care of Dr. Taber Johnson. There was no stenosis of the cervical canal; no tenderness or enlargement of the ovaries could be detected by bimanual examination. A slight displacement was corrected. There was no dysmenorrhœa. The convulsions persisted for days, and sometimes there was episthotonos. Bromides alone would not produce sleep, and he was compelled to resort to brandies and chloral. Her mother said inhalations of chloroform had been tried. Dr. Hamilton was strengthened in his determination to operate by hearing the paper of Dr. Gordon. The day Dr. Hamilton operated the patient was unconscious and had been so for days. She has had no paroxysm since the day following the operation. He believes acute mania would have resulted if he had not operated. She would have had cerebritis, followed by death. The removed ovaries were both cystic. One was larger than the other. The left one was adherent in the basin of the pelvis. Had she lived she would undoubtedly have had an ovarian tumor. It is not fair to decry the operation because every case does not recover from all the symptoms. How often would we operate for scirrhus if we waited until entire relief followed? *Materia medica* does not seem to be efficient in these cases. Dr. Hamilton desired a description of a normal cyst. Cysts are composed of abnormal tissue, and are always pathological. It may be that those who perform this operation will live to regret it; but they ought not to be deterred because every case does not get well, and they can derive comfort from the results of Gordon and Wylie.

DR. J. FORD THOMPSON had no experience with this operation. He thought, however, that there is no operation so clouded in doubt. Of course it may be necessary in cases of fibroids to stop excessive hæmorrhage; but in the case of young girls, it is our

bounden duty to be convinced that this operation, and this operation alone, will result in a cure, before we undertake to deprive them of such important organs. Men are not castrated unless some serious disease of the testicles is plainly made out. Symptoms such as these girls had may be caused by regional or local troubles. Laceration of the cervix or displacement of the uterus has been said to produce such symptoms. Hysteria may be present without ovarian disease.

Dr. Thompson related the case of a woman now under his care. He had cured a bilateral laceration of the cervix without relieving her symptoms. In making further examination he ruptured a cyst. On the left side there is a displaced ovary. On the right side he detected a movable body which proved to be an ante flexed uterus, the fundus being almost as low as the cervix. This ante flexion may be the cause of her troubles. But she has heard of oöphorectomy and I presume she will eventually find somebody who will gratify her desire to have it performed upon her. To say that a cyst is pathological does not imply that it is the cause of such symptoms as lead Drs. Johnson and Hamilton to operate on these young girls. Gynecologists operate upon subjective symptoms and find the ovaries practically healthy. To say that the ovaries are cystic will not account for the symptoms, for either of these patients might have had an ovarian cyst weighing many pounds and yet never have suffered a moment from any such symptoms. Surgeons do not thus operate for the removal of the testicles. They must have something more definite than nervous phenomena presumably coming from the testicles. Indeed, they recognize no such symptoms. To prove the efficacy of oöphorectomy the result of many operations performed a sufficiently long time ago must be recorded. Dr. Gordon's cases were operated upon too short a time since. The length of time since the inception of the operation is too short to prove much. Every method of treatment must be persistently tried. The younger the patient the longer he would hesitate about performing so serious an operation as the unsexing of a woman.

DR. S. C. BUSEY said that while he was not opposed to oöphorectomy and would counsel its performance if convinced of its necessity in any particular case; yet it was becoming so popularized that many thoughtful minds considered it time to call a halt before every woman with nervous disturbances should have her ovaries removed. He agreed with Dr. Thompson that the younger the patient the longer we should hesitate. He had seen cases similar to the one related by Dr. Hamilton, that got perfectly well after marriage and pregnancy. In response to Dr. Hamilton, Dr. Busey narrated a case in point. The patient had suffered from convulsions since her 14th year. They continued for six years, sometimes lasting three days. She married three years ago, has a baby 18 months old and will soon become the mother of another. She has never had a convulsion since the beginning of the first pregnancy. He said that is only one of several cases. The mere fact that a woman has her abdomen opened and recovers with-

out a bad symptom proves nothing but the skill of the surgeon and the perfection of technique. The first operation was performed by Battey thirteen years ago. Surely surgery ought to be able to give us some statistics and facts showing a sufficient ratio of permanent cures in order to establish the operation on a pathological basis. Dr. Busey said he was not referring to operations for the relief of pyosalpinx and fibroid tumors, but to operations for the cure of nervous disturbances of obscure origin. Charcot and Weir Mitchell have cured many such cases without unsexing the woman.

Dr. Busey thought we should have some better means of diagnosis than the ovaries shown on a dinner plate. It is very easy to say that failures should not be charged in this operation any more than in typhoid fever. There is no parallelism. He desired to know the number permanently cured in the last thirteen years; and if the number of years added to the lives of the cured would counterbalance the lives lost. He had no doubt cases had been cured; but how many? That twenty-five operations have been performed in six months by one man proves nothing. There is a very considerable reaction taking place. There is hardly a medical journal that does not contain a paper deprecating the popularization of the operation. Dr. Emmett has seen only two cases in which he thought the operation advisable, and both patients recovered under other treatment. Others were now declaiming against the too great frequency of the operation. The mere statement that a macroscopic examination shows the ovary to be undergoing cystic degeneration does not prove much. What we want to learn is the pathological changes in the normal tissues of the ovary. Prominent men with large opportunities have declared that it is a rarity to see a perfectly healthy ovary. Dr. Busey in conclusion said he wished it to be understood that he had no desire to criticise the two cases reported to-night. His remarks, he said, applied to the operation in general.

On motion further discussion was postponed until the next meeting, at which¹ DR. JOSEPH TABER JOHNSON replied as follows:

As the further discussion of this subject was postponed until the next meeting, on account of the lateness of the hour, thus preventing me from replying to the criticisms upon my operation, and to the various questions asked me during the debate; and, as I shall be unable to attend the next meeting of the Society to "close the discussion," the Secretary has kindly offered to read any reply which I may desire to write. In accepting this offer, I beg to say first in reply to Dr. Smith's question about the former treatment of my patient, that I refer him to the remarks of Dr. Kleidschmidt, who had her under his care long enough to demonstrate to his entire satisfaction the uselessness of further treatment. He found no stenosis of the os or cervical canal; no uterine displacement and no vaginal disease; no tenderness or inflammation. Neither did I. She had no uterine disease. She had been treated for ordinary epilepsy, which, curiously enough, annoyed

her mostly at the time of her monthly periods. That and the ovarian pain is all the disease she had. I have ventured to call it menstrual epilepsy, and to call many of her other symptoms hysterical.

She had had treatment in abundance during the years of her life from 12 up to date of operation, covering a period of fully seven years. She had been blistered and purged, and puked, mercurialized and narcotised, made stupid and idiotic for weeks by the bromides up to a daily dose of 300 grs.; had been kept in bed for two months by Dr. Baker, and no good result followed, and she was getting worse. She saw, and her mother saw, that all this had done no good. She was no better, she says, after a course of treatment, by Dr. Murphy, though she enjoyed some temporary benefit while under his care. She "had taken gallons and gallons of medicine," and with what result? She was getting worse instead of better; she was becoming a helpless invalid. On one occasion she fell in the fire and narrowly escaped a terrible death. She had constantly to be watched and guarded.

When the operation was first proposed by Dr. Kleinschmidt the girl was ready to have it done, as it offered some hope out of the darkness and suffering of her now hopeless life; but her mother said, "No, she would see her die first." But they finally came and begged for it.

Dr. Hamilton has answered Dr. Smith's question in regard to whether a "cystic ovary" can be healthy. I believe such ovaries are pathological. The good Lord never made any woman with ovaries in a state of "cystic degeneration," a term which the microscopists and pathologists are now ridiculing. Men may have mistaken graafian vesicle for a cyst, and a corpus luteum for evidence of degeneration. So have the microscopists mistaken ascetic for ovarian fluid, and operations have been performed on their recommendation when no ovarian tumor was found. So they have condemned patients to death on account of supposed cancer, and the patients have lived to laugh at their mistakes. A pathologist finds many curious post-mortem appearances. His "hind-sight is better than our fore-sight" sometimes. He has the advantage of us. He can deliberately open an abdomen with no fear of hæmorrhage or injuring an intestine; indeed, if the intestines are in his way he punctures them and lets out the gas. He looks at the ovaries and tubes of a woman who has been dead twenty-four hours or more. They are pale as death. He sees no congestion or quivering nerves, no inflammation, there is no tenderness, or outcry when the slightest touch is made. There is no complaint of the thousand and one symptoms which this congested, tender, sensitive, live, palpitating organ gave rise to during life, and the pathologist says there was little or nothing the matter; and the microscopist, after keeping an enlarged, congested, much red-dened cystic ovary in alcohol a month or two, sees very little in the pale, shrunken, shriveled organ before him to have occasioned so much trouble; but let them treat a few of these cases for eight or ten years without benefit, and have them *plead for something*—no matter how uncertain, no matter how risky

¹ Date not given in official report.

or dangerous, which offered *any* hope, or had *ever cured anybody else*—to be *done* for *them*, and their views about these matters might undergo some change. I operated on this girl after reading the favorable cases reported by Gordon. I thought his a precedent which I could follow. Surgeons do more than this, when the spleen or the kidneys, or portions of the stomach or intestines have been found the seat of otherwise incurable disease; they have opened the abdomen and removed the offending organs, in whole or in part when there were fewer cases as precedents than I had to follow, and the operations were more dangerous and more frequently fatal. I think I am prepared to say that if there were twenty or fifteen or even ten such cases as the one I have reported, cured by this operation, and I was certain that mine was the counterpart of them, and the patients fully understood the nature of the operation, its dangers and uncertainties, and still appealed to me to operate, that, being convinced that there was a fair chance of recovery, I would give it to them, notwithstanding the objections of a thousand physicians who had nothing better to offer.

I think Dr. Hamilton did right to operate. I am not sure the sequel will show. I saw his patient and treated her for some time in his absence. She had no uterine disease; she had no painful menstruation; no displacement which had not been corrected. She was growing worse; she was in a terrible condition. Much anxious thought was given to her case. I think she actually stood in more danger from the chloral and chloroform necessary to secure quiet or sleep for herself or her family, than she did from the operation. I think more patients have died from the effects of these remedies given to relieve pain or stop convulsions than from the effects of this operation.
